FOREWORD

This report summarizes the work accomplished by the Aircraft Division of Northrop Corporation, Hawthorne, California for the Air Force Flight Dynamics Laboratory, AFSC, Wright Patterson Air Force Base, Ohio, and USAF Contract No. F33615-69-C-1602 (Project 698 BT). This document constitutes the Final Report under the contract.

This work was accomplished during the period 1 May 1969 to 31 January 1972, and this report was released by the authors in January 1972. The Air Force Project Engineers were Mr. Robert Nicholson and Mr. Henry W. Woolard of the Control Criteria Branch, Flight Control Division, AFFDL. Their assistance in monitoring the work and providing data is greatly appreciated.

The authors gratefully acknowledge the assistance and cooperation of NASA Langley Research Center personnel during the wind tunnel model testing in the NASA Langley V/STOL tunnel.

Special recognition is due Mr. Richard J. Margason of NASA Langley Research Center who, besides being actively involved in the testing at Langley, has made valuable contributions to other areas of the investigation.

Various people at Northrop's Aircraft Division contributed to the investigation, particularly the following persons in the areas designated:

Lynn B. Fricke	Devel	oped empirical	methods	for the	wing.	Was Te	st
----------------	-------	----------------	---------	---------	-------	--------	----

Engineer for the wind tunnel testing of the component

model.

Hsiao C. Kac Developed the transformation method for estimating

power effects on wings and fuselages. Developed the

empirical method for the body.

Myles F. Schwendemann Developed the method for estimating engine inlet effects.

Provided prediction method wind tunnel testing interface

for the configuration model. Participated in the hover

analysis.

Martin F. Silady Assembled the V/STOL bibliography and was responsible

for the literature survey.

Howard R. Wasson Developed the method for mapping general sections.

Developed the nonlinear body prediction method. Assisted

with the development of the perturbation method.

Peter T. Wooler Directed the technical effort and developed the nonlinear

wing prediction method.

Henry Ziegler Developed the jet flow field prediction method. Per-

formed the analysis of wing power effects employing

lifting surface theory.

Contributions have also been made by U.A.G. Brynjestad to this study in a number of areas, particularly the literature search and perturbation method development; by M.S. Cahn in the development of the method for mapping general sections and perturbation method development; by members of the Northrop Aerosciences Laboratories in respect to model design, fabrication, testing and data reduction — especially T. Comerinsky, F. W. Peitzman, E. G. Kontos and W. S. Ramos.

This report contains no classified information.

ABSTRACT

Analytical engineering methods are developed for use in predicting the static and dynamic stability and control derivatives and force and moment coefficients of lift-jet, lift-fan, and vectored thrust V/STOL aircraft in the hover and transition flight regimes. The methods take into account the strong power effects, large variations in angle of attack and sideslip, and changes in aircraft geometry that are associated with high disk loaded V/STOL aircraft operating in the aforementioned flight regimes. The aircraft configurations studied have a conventional wing, fuselage and empenage. The prediction methods are suitable for use by design personnel during the preliminary design and evaluation of V/STOL aircraft of the type previously mentioned.

This report consists of four volumes. The prediction methods are applied to a number of V/STOL configurations in this volume. The theoretical development of the prediction methods may be found in Volume I. Details of the computer programs associated with the prediction methods are given in Volume III. The results of a literature survey are presented in Volume IV.

SECTION I

INTRODUCTION

This volume is the second of three volumes treating V/STOL Aerodynamic prediction methods. This volume is directed toward presenting applications of the methods developed during the study program. These applications represent the complete prediction techniques developed except for empirical methods for treating power effects on wings and bodies which are presented in Volume I.

1. PURPOSE

The purpose of this volume is to demonstrate the use of the prediction methods in computing the aerodynamic coefficients and derivatives of V/STOL aircraft. To accomplish this purpose example problems are worked out using the prediction techniques. The accuracy of the methods can be assessed by comparing the predicted aerodynamic coefficients against test results. Limitations of the methods are described and the necessary assumptions and simplifications which must be made are pointed out. It should be possible for the user to evaluate the described methods and to assess their limitations for use in his problems by examining the included sample problems.

2. SCOPE

The methods which are applied in this volume represent the theoretical prediction techniques which have been developed during the study contract. The one theoretical thechnique which is not presented is the vortex tracking method which is not applied to a given example problem since the method was not operable. Also not included in this volume are the empirical methods for treating wing or body. These methods are treated completely in Volume I.

In presenting samples of the use of the method the specific nature of the chosen problem often does not demonstrate the full capability of the methods being employed. To further demonstrate the method capabilities it is frequently pointed out where the methods are more general and where different problems can be treated by the same methods.

3. TECHNICAL APPROACH

The method of demonstrating the application of the individual methods which was adopted for this volume was to select a sample problem and to apply the methods to this problem where applicable. The details involved in using each method are explained by presenting a complete treatment of the sample problem. Where computer programs are involved complete inputs, outputs and comparison of results with experiments are presented. Where computer programs are not involved the equations used are presented and comparison with experiment is presented.

Sample problems have been chosen where test data is available for comparison with theoretical results. This permits the accuracy of the prediction techniques to be evaluated and permits a better understanding of the difficulties to be encountered in predicting the aerodynamics of V/STOL aircraft.

4. ORGANIZATION OF VOLUME II

The main body of Volume II is devoted to sample problems treating V/STOL aircraft configurations. The treatment is divided into sections considering the power induced effects and the power off effects.

Section II presents two methods of treating power effects on the wing of a V/STOL configuration. Each of these methods has certain advantages for the user and both will be useful in treating power induced effects on wings.

Section. III presents the method of predicting power induced effects on the fuselage and illustrates the accuracy which can be obtained.

Section IV demonstrates the use of the prediction methods in obtaining downwash and sidewash effects at the empennage location and illustrates how these results can be used to estimate power effects on the tail surfaces.

Section V presents the method applicable to predicting the power effects of the inlets. Comparisons are made with test data to illustrate the accuracy of the method.

Sections VI and VII present the methods for treating the unpowered effects of nonlinear body and wing aerodynamics. Section VI presents the nonlinear body method and shows comparisons with test data. Section VII presents similar comparisons for wing aerodynamics.

Four appendices are added to this volume to complete the documentation of work performed under the contract. The first three appendices describe the wind tunnel test program undertaken during the study. This description is presented in this volume to permit the details of the test program and model description to be available to the user. This is desirable since much of the test data used for comparison with the prediction method came from the test program. A method for estimating normal force and pitching moment in the lift jet wake region is presented in Appendix IV.

SECTION II

POWER EFFECTS ON THE WING

There are two alternative procedures for computing the power induced effects on the wing. The first of these combines the mapping method, the jet flow field program and the transformation method. In this method the mapping program is used to describe the wing, the jet program calculates volocities induced by the jet at the wing surface and the transformation method calculates pressures, forces and moments induced by the jet on the wing.

In the second procedure the jet program is used in conjunction with the lifting surface theory to predict power induced wing effects. The jet program computes a downwash field at the wing plane which gives an effective camber distribution for the wing. The lifting surface theory then ctilizes this camber distribution to compute lift and pitching moment on the wing. This method does not give the pressure distribution about the wing but is simpler and easier to use than the first method.

The following subsections will describe the use of both of these methods as applied to a given wing. The use of the methods will be described in detail so that a complete understanding of the methods can be obtained.

1. SAMPLE PROBLEM

To demonstrate the method of predicting the power induced aerodynamic effects on a wing, a sample problem is given. This problem is for a single jet in the presence of an isolated wing. The wing of the samile problem is the one tested in the configuration wind tunnel test program discussed in Appendix I.

Wing Description:

Root chord:

10.733 inches

Tip chord:

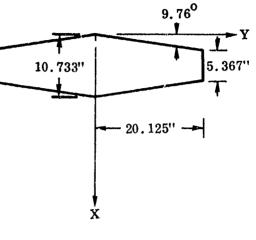

5.367 inch as

Semispan:

20.125 inches

Leading Edge sweep: 9.76 degrees

Section: NACA 63A010 at all wing stations

Section coordinates:

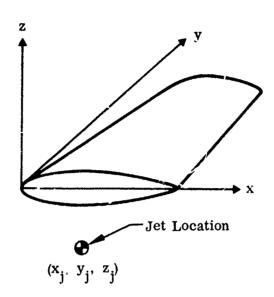

x (Percent c)	z (Percent c)
0	0
0.25	0.555
0.5	0.816
0.75	0.983
1, 25	1.250
2.5	1.737
5.0	2.412
7.5	2.917
10	3,324
15	3.950
20	4.400
25	4.714
30	4.913
35	4.995

x (Percent c)	z (Percent c)
40	4.968
45	4.837
50	4.613
55	4.311
60	3.943
65	3.517
70	3.044
75	2,545
80	2.040
85	1.535
90	1.030
95	0.525
100	0.021

Leading Edge radius 0.742 percent c

Jet location and description:

A sketch of the coordinate system defining the jet location relative to the wing is shown below.

For the sample problem:

$$x_j = .6$$
 inches $y_j = 0$ $z_j = -6.635$ inches (positive upward)

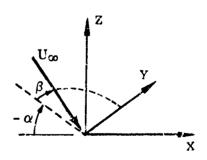

Jet diameter $d_j = 2.25$ inches

The jet exhausts into the mainstream along the negative z-direction, that is perpendicular to the wing planform.

Velocity ratio
$$\frac{U_{\infty}}{U_{J_0}} = .2$$

Wing attitude:

Angle of attack
$$\alpha = 0$$
 degrees
Sideslip angle $\beta = 0$ degrees

2. APPLICATION OF MAPPING METHOD TO THE WING $_{\scriptscriptstyle S}$

about propular account of this included and ordered account account of the accoun

In the sample problem all the wing sections are geometrically similar so that it is only necessary to map a single section and then to scale the coefficients to provide a mapping for different spanwise stations. Figure 1 shows the inputs to the mapping program used to obtain the initial mapping.

The first card lists in order the number of coordinates being input, the number of corners (and pseudo-corners) being input, the number of terms to be taken in the expansion for the potential and the mapping, and a zero to indicate that the section being mapped is symmetrical about the x-axis.

Cards 2 through 5 give the x-coordinates selected as input points starting at the section trailing edge and proceeding around to the nose. Cards 6 through 9 are the z-coordinates of the airfoil at the same points. Since the section is symmetrical only the upper half plane coordinates are input.

Card number 10 specifies that the airfoil is to be shifted .5 units in the negative x-direction. This is necessary since to obtain the mapping it is necessary that the airfoil be centered with respect to the origin to some degree. It is not necessary to center the section exactly but it should be centered somewhere near the centroid of area.

Card 11 specifies which input points are corner points. This card indicates that the first input point (the trailing edge) is a corner point. The second number, the zero, indicates that the second corner is a pseudo-corner; that is, is not a true corner but merely indicates a region of large curvature. This second number refers to the nose of the airfoil.

Card 12 specifies the x and z coordinates of the first corner and the angle turned through at the corner in radians.

Card 13 similarly describes the second corner specifying the location of the center of the leading edge radius and specifying that a corner of π radians is turned. This angle turned is only an approximation; it is not necessary to specify the angle exactly.

Card 14 specifies parameters needed to tell the program how to write out the mapped section with the corners included. The first two numbers are the x- and z-coordinates of the initial point to be mapped, in this case the leading edge point. The third and fourth numbers specify the first and last points to be mapped specified as angular distances around the mapping circle. In the the sample section the mapping is to start at the nose (180 degrees) and proceed around the lower surface until just

FIGURE 1. MAPPING PROGRAM INPUT DATA FOR SAMPLE PROBLEM (Wing)

ahead of the trailing edge (355 degrees). The last number specifies that mapped points are to be obtained at increments about 5 degrees apart. In this example, it was necessary to choose these parameters to avoid specifying the trailing edge as one of the end points. This is because the trailing edge is a corner and a corner point cannot be specified as one of the end points.

Card 15 specifies the necessary parameters needed to map out points on the section with the corners removed. This card specifies that 37 points are to be printed out with a spacing increment of 5 degrees about the mapping circle and that the mapping is to start at $\theta = 0$ degrees on the mapping circle.

The outputs of the mapping functions for the inputs of Figure 1 are shown in Figure 2. The first page of outputs, Figure 2(a), relates to the computations made in calculating the potential and the point-to-point correspondence between points on the section and points on the mapping circle.

The first two columns represent x- and y-coordinates of the input points with the x-coordinate shifted by the incremental value of ΔX input (in this case, -.5). The third column represents the distance, R, from the new origin to the point on the section. The fourth column gives the computed perimeter, S, of the section from the positive real axis to the point in question. The fifth column gives the velocity, V, calculated due to the unit vortex about the body. The velocities written out for corner points are meaningless. ALPHA is the angle of the section slope at each point as calculated in the program. OMEGA specifies the angular distance in degrees around the section measured about the new origin. THETA is the predicted angular distance of the points around the mapping circle in degrees.

The second page of printouts, Figure 2(b), represents the results obtained by computing the derivative of the mapping function with the corners contained explicitly and integrating the resulting expression numerically. The location of the first point was specified as explained above (this point is not printed out). The three columns give the x-coordinate, the y-coordinate and the angle around the mapping circle θ for a series of points as specified by the parameters specified in the input cards. The degree to which these points agree with the original section represents the degree of accuracy obtained by using the mapping method.

The third page of outputs, Figure 2(c), represents the results of multiplying out factors representing any corner singularities and integrating the resulting expression analytically.

CCMPUTATIONS FOR S AND ALPHA VERSUS THETA.

(d) MAPPING OF SECTION WITH CORNERS REMOVED

Military operation of the control of

FIGURE 2. (Concluded)

First, the radius of the mapping circle is printed out as computed. Next, the coefficients of the mapping function are written out – first the real parts a_n — then the imaginary parts b_n . The mapping function is written in the form

$$Z = \zeta + \frac{a_1 + ib_1}{\zeta} + \frac{a_2 + ib_2}{\zeta^2} + \cdots + \frac{a_n + ib_n}{\zeta^n}$$

The coefficients are written out in order a_1 , a_2 , a_3 a_n and for this particular case, all the imaginary parts of the coefficients are zero since the section is symmetrical.

Page four, Figure 2(d), prints out the x- and y-coordinates obtained with the analytically integrated mapping function. It is not possible to obtain the location of the body directly by this method of computation; i.e., the constant term in the above mapping is missing. This prevents the location of the section being mapped from being specified. This is readily remedied by plotting the original section and the mapped section and the displacement required to obtain a good fit between the two sections represents the constant term of the mapping.

Figure 3 shows a comparison between the mapped output and the original input section, the lower surface also being shown since the section is symmetrical and the mapping retains the property of symmetry.

To obtain coefficients for the wing of the sample problem it is necessary to change the coefficients to account for the size of the actual wing. The coefficients of Figure 2 are based on a unit chord and the mapping for this section can be written:

$$\frac{Z}{c} = \zeta_1 + \overline{a}_0' + \frac{\overline{a}_1'}{\zeta_1} + \dots + \frac{\overline{a}_q'}{\zeta_q'}$$
(1)

where

motarementarian includence of a constitute and include the section of the section

$$a' = .60815 \times 10^{-1}$$

$$a'_{2} = .75779 \times 10^{-3}$$

$$a'_{3} = .69368 \times 10^{-4}$$

$$a'_{4} = .12786 \times 10^{-6}$$

$$a'_{5} = -.23231 \times 10^{-6}$$

$$a'_{6} = 15404 \times 10^{-6}$$

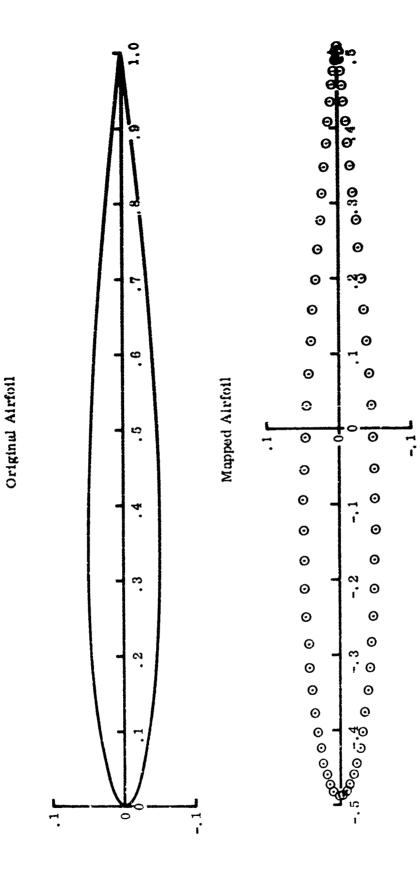

FIGURE 3. COMPARISON OF ORIGINAL AND MAPPED AIRFOIL

$$a'_7 = .11822 \times 10^{-7}$$
 $a'_8 = -.46527 \times 10^{-10}$
 $a'_9 = -.44950 \times 10^{-9}$

and

$$\zeta_1 = r_c' e^{i\theta}$$
 $r_c' = .26916$

a' has not been determined and it is best to leave this coefficient undefined until the coefficients have been ratioed up to true size.

It is desired to reexpress Equation (1) in the form:

$$Z = \zeta + \partial_0 + \frac{\partial_1}{\zeta} + \dots + \frac{\partial_q}{\zeta^q}$$
 (2)

where the coefficients a_0 , a_1 , a_2 , a_9 reflect the true wing dimensions at given stations along the wing. Rewriting Equation (1) in the form

$$Z = \zeta + d_0 + \frac{a_1}{\zeta} + \dots + \frac{a_q}{\zeta^q}$$

and equating $c_1 \zeta_1$ to ζ we obtain

$$Z = \zeta + ca'_0 + \frac{c^2a'_1}{\zeta} + \frac{c^3a'_2}{\zeta^2} + \dots + \frac{c^{10}a'_9}{\zeta^9}$$

so that it can be shown that

$$a_n = c^{n+1} a'_n$$
 $n = 1, 2, \dots, 9$

The radius of the new mapping circle defined by $\xi = r_c e^{i\theta}$ is now $r_c = cr'_c$

To obtain the coefficient a it is sufficient to note that from the first and last numbers of the last page of Figure 2, the mapping without the constant coefficient maps the section about a chordwise point of .4891, so that for the origin of the wing located at the

nose of the root chord and a leading edge sweep of 9.76 degrees, the coefficient $\mathbf{a}_{_{\rm O}}$ can be found as

$$a_0 = .4891c + y \cdot tan 9.76 degrees,$$

where
$$c = c_r - (c_r - c_t) y/b/2$$

For use in the transformation method, it is also necessary to define $\frac{dr}{dy}$ for the wing. This can be done by noting that

$$r_c = .26916 c$$

$$\frac{d\mathbf{r}_{\mathbf{c}}}{d\mathbf{y}} = .26916 \frac{d\mathbf{c}}{d\mathbf{y}}$$

K is now possible to compute all of the numbers needed for the transformation method.

These numbers are tabulated in Table 1.

3. APPLICATION OF JET FLOW FIELD THEORY TO WING

a. Transformation Liethod

The purpose of the Jet Flow Field theory, when used in conjunction with the Transformation Method, is to predict jet-induced velocity components at those control points on the wing at which the Transformation Method requires them to evaluate power effects. This is accomplished by executing the Jet Flow Field computer program to generate the required data for the Transformation Method in the form of punched data cards. To insure compatibility with the Transformation Method, the control points on the wing are specified by utilizing the mapping coefficients for the wing cross sections obtained by the procedure described in Section II.2. The punched output is generated in a manner to provide a continuous block of input data to the Transformation Method computer program. Both of the above features will be described in greater detail in the discussion below.

(1) Sample Problem Computation

For the sample problem being considered, the Jet Flow Field program is now used to compute the jet-induced velocities at the eight spanwise stations on the wing described in Section II.2. Figure 4(a) shows a sketch of the wing and the location of the jet with respect to the input/output coordinate system. Figure 4(b) defines the jet exhaust angles ϕ and ψ . It should be noted that the input/output coordinate system shown below differs from the general coordinate system utilized in Section II, Volume I.

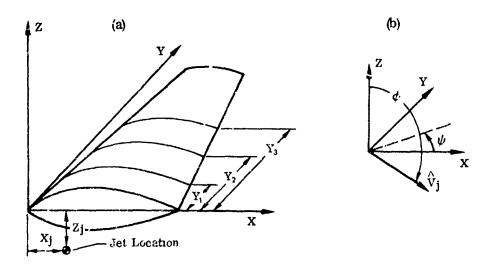

FIGURE 4. COORDINATE SYSTEM FOR TYPICAL WING

(a) Input for Sample Problem

The input cards required for the sample problem are tabulated in Figure 5.

Card 1 lists three control indices. The first one, MULT = 1, indicates that a single jet configuration is being treated. The second one, IGEØM = 1, specifies that control points on wing cross sections will be generated, utilizing the mapping coefficients obtained in Section II. 2. The third control index, IPUNCH = 1, generates the punched output for the Transformation Method program.

Card 2 specifies angle of attack $\alpha = 0$, and angle of sideslip $\beta = 0$.

Card 3 controls the number of steps and the step size in the numerical integration of the equations of motion for the jet path. For the sample problem, 90 steps with a step size of 0.4 jet exit diameters are chosen.

Cards 4 and 5 contain information about the jet. The jet location in the coordinate system of Figure 4 is X = 0.6, Y = 0., Z = -6.63. The jet exhaust angles ϕ and ψ , defined in Figure 4(b) are 180 and 0 degrees respectively. The jet exit diameter, $d_0 = 2.25$ and the velocity ratio $U_{\infty}/U_{i_0} = 0.2$.

Card 6 may be left blank for computations revolving a single jet. For a multiplejet configuration it would be used to control the geometry of the jet resulting from the intersection of two other jets.

The remaining input cards provide data to generate the control points at which jet-induced velocities are to be evaluated. These control points are generated by utilizing the mapping coefficients and mapping radii obtained in Section II.2 for the eight wing stations of the sample problem. The number of control points generated at each spanwise station is governed by the input variable NTHT, which is the number of increments $\Delta \theta$ into which the mapping circle is to be divided in the Transformation Method computer program.

Card 7 specifies that NTHT, the number of control points at each spanwise station or the number of $\Delta\theta$ increments around the mapping circle is 36, and that the number of spanwise stations NS =8. It also defines the number of terms used in the mapping expansion of Section II.2, NCØEF = 11, and through the control index IRECT = 1 indicates that the wing is nonrectangular.

Cards 8-12 provide the data from which the wing cross section at the first spanwise station can be generated by the computer program. Card 8 specifies the location of the station, Y=0, the mapping circle radius R=2.8889 and the rate of

FIGURE 5. JET FLOW FIELD PROGRAM INPUT DATA FOR SAMPLE PRUBLEM (Wing; Transformation Method)

change of R with Y, DRDY = 0. Cards 9-12 list the real and imaginary parts of the coefficients to be used in the mapping expansion. Cards 13-47 are similar data blocks for the spanwise stations Y = 2.5, 5.04, 7.7925, 10.545, 13., 16.05 and 20.125. The data in cards 8-47 are taken from the Table I in Section II.2.

Note: The rate of change of the mapping circle radius with spanwise distance, DRDY, is not required for any of the computations performed by the Jet Flow Field program. It will, however, be required by the Transformation Method program and is read as part of the input that it may be punched out in the proper sequence in the data package to be provided to the Transformation Method program.

(b) Output for Sample Problem

For the problem being considered both printed and punched outputs are obtained.

Printed Output:

Figure 6(a) shows the first page of printed output. The jet configuration being treated is identified both by appropriate heading and by other pertinent input information. Input controlling the numerical integration procedure is also displayed. Figure 6(b) shows the location of the computed jet centerline. The nondimensionalized jet speed U_i/U_{io} and the nondimensionalized major diameter of the ellipse representing the cross section of the jet, d/do are also printed out. These properties are printed out at each integration interval. Output shown in Figure 6(b) shows only the initial portion of the printed output generated for this example. The centerline was computed to Z = 87.63, which represents integration of the jet equations over the range Z = 90 x 0.4 x 2.25 = 81. The variables XCOORD and DIA show a monotonic increase over this region, while UJ = $U_j/U_{j_0} \approx$.2 as the mean jet speed approaches the freestream speed U... Figure 6(c) shows the printout for the jetinduced velocity components at the first spanwise station specified, Y = 0. The coordinates of the 36 control points at the station are identified. The induced velocity components U, V, W all nondimensionalized by U, are printed out for each control point. Figure 6(d) shows the output for the last station considered in the sample problem, Y = 20.125. Similar printouts are obtained for the other intermediate stations specified as part of the input.

FIGURE 7. (Concluded)

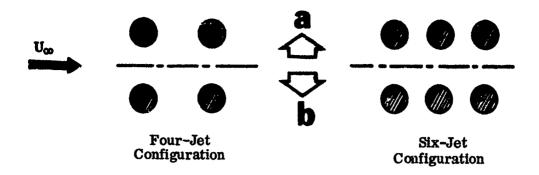

Punched Output:

The punched card output for the sample problem is shown in tabulated form in Figure 7. The output data block for the first spanwise station is identified. The first card lists the spanwise station Y = 0, the mapping radius R = 2.8889 and the rate of change of R with Y, DRDY = 0. The next four cards list the real and imaginary parts of the coefficients used in the mapping expansion. Cards 6 - 11 list the induced velocity components in the X direction for each of the 36 control points at Y = 0. The induced velocity components in the Y-direction are listed on cards 12 - 17 and cards 18 - 23 specify induced velocity components in the Z-direction. Data blocks of this type, each consisting of 23 cards, follow for each of the other 7 spanwise stations specified as part of the input. The punched output is identified in columns 73 - 80. The spanwise station number is shown in columns 75 - 77. Sequence numbers for each station appear in columns 78 - 80. The letters U, V, W in column 74 identify the velocity components listed on the data cards.

Note: From the tabulations of Figure 7 it is apparent that the first five cards of the data generated for each spanwise station represent an exact duplication of input cards described previously. They are generated as part of the punched output so that a more complete data package for the Transformation Method program may be obtained and additional card handling circumvented.

(2) Applicability and Limitations

The Jet Flow Field program may be utilized to evaluate the induced flow field at given control points due to one, two or three exhausting jets. For a single jet the initial jet exhaust direction, specified by ϕ and ψ , and the freestream direction, specified by α and β are arbitrary. For a two-jet configuration the jet exits must both lie in the same XY plane and the jet exhaust planes, defined by the freestream vector and the initial jet exhaust vectors, must be parallel. The same restrictions apply to a three-jet configuration. Additionally, three-jet configurations must be colinear and negative angle-of-attack cases cannot be treated. More complex configurations, as shown below, may be treated by reduction to two- or three-jet type configurations, as indicated, and adding the induced velocities at each control point due to configurations (a) and (b).

Extensive comparisons between computations and experimental data have been made for velocity ratios $0.10 < U_{\infty}/U_{jo} < 0.30$ and the Jet Flow Field program may be considered most applicable in this range of velocity ratios.

The choice of the variables governing the numerical integration for the jet path is related to the velocity ratio of the problem being considered. For $U_{\infty}/U_{jo} < 0.125$ integration in the direction normal to the freestream over an extent of at least 30 jet exit diameters has been found desirable. As U_{∞}/U_{jo} increases this may be decreased, as the jet penetrates less at the higher velocity ratios. For the above range of velocity ratios an integration step size of ≤ 0.5 jet exit diameters has been found satisfactory.

Control points at which jet-induced velocity components are to be evaluated may not lie within the jet itself, as the Jet Flow Field theory is not valid in this region.

Generally, control points positioned less than 2 jet exit diameters from the center of the jet exit should be avoided, to avoid distortion in the computed velocity distributions.

b. Lifting Surface Theory

The purpose of the Jet Flow Field theory, when used in conjunction with the Lifting Surface theory, is to predict jet-induced downwash distributions on the wing to be utilized by the Lifting Surface theory in evaluating power effects. This is accomplished by executing the Jet Flow Field computer program to generate required input data for the Lifting Surface program in the form of punched data cards. These data cards will then constitute the downwash matrix [W], which forms part of the input for the Lifting Surface program described in Section II.5.

It should be noted that the manner in which the Jet Flow field program is utilized to provide date for the Lifting Surface program is almost identical to its application in

conjunction with the Transformation Method described in Section II. 3. a. The discussion below will treat in detail only those areas of input and output which differ from Section II. 3.a.

(1) Sample Problem Computation

For the sample problem being considered, the Jet Flow Field program is now used to compute jet-induced downwash distributions at 10 spanwise stations on the wing. Figure 8 shows details of the planform of the wing and indicates the network of control points to be utilized in the computations.

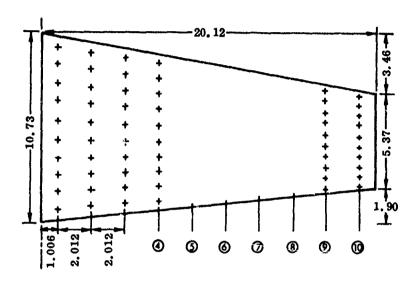

FIGURE 8. CONTROL POINTS ON WING FOR SAMPLE PROBLEM

The wing is treated as a planar surface, Z = 0. Each spanwise station has 10 control points spaced evenly between 0.05 and 0.95 of the local chord. The spanwise stations are distributed evenly between 0.05 and 0.95 of the semi-span.

(a) Input for Sample Problem

The input cards required for the sample problem are tabulated in Figure 9.

Card 1 again lists the three control indices. IGEØM = 3 indicates that the coordinates of all control points will be provided directly as part of the input. The other two indices remain unchanged from Section II. 3. a. The punched output generated will, of course, now be suitable for use with the Lifting Surface program.

Card 2 remains unchanged from Section II. 3. a.

FIGURE 9. JET FLOW FIELD PROGRAM INPUT DATA FOR SAMPLE PROBLEM (Wing; Lifting Surface Theory)

Card 3 controls the number of steps and the step size in the numerical integration of the equations of motion for the jet path. For this case, the number of steps has been cut down to 50, as computations in Section II.3. a showed that after a penetration of 20 jet exit diameters into the crossflow, the nondimensionalized jet speed $U_j/U_{jo} = 0.202$, i.e., the jet has virtually slowed to the speed of the crossflow and further contributions to the jet-induced velocities will be negligible.

Cards 4-6 see Section II. 3. a.

Card 7 lists the number of spanwise control stations, NS = 10 and specifies that the number of control points at each station NC = 10.

Cards 8-57 list the coordinates for the control points of the grid shown schematically in Figure 8. The coordinates for each control point appear in the order X, Y, Z. Control points are listed from leading edge to trailing edge for each spanwise station, with the spanwise stations appearing in a root-to-tip sequence. The total number of control points is NC x NS. The listing is continuous, i.e., no new record is required for the first control point at each spanwise station.

(b) Output for Sample Problem

Both printed and punched outputs are obtained.

Printed Output:

The initial part of the printout dealing with configuration identification and jet centerline printout will be identical to that shown in Figures 6(a) and 6(b) of Section II.3. The centerline computations are now carried out to Z = 51.63 consistent with the 50 integration steps specified. Figure 10 shows a portion of the printout for the jet-induced velocity components at the control points specified as part of the input. The control points are listed in the order in which they were read in. All three velocity components are printed out, although only the downway h component W needed in conjunction with the Lifting Surface theory.

Punched Output :

The punched output for the sample problem is shown in tabulated form in Figure 11. The data block for the first spanwise station is identified. The cards list the downwash component -W, nondimensionalized by U_{∞} , for each control point at the first spanwise station in a leading to trailing edge

FOR SAMPLE PROBLEM
(Wing; Lifting Surface Theory)

sequence. The sign of W is changed to provide compatibility with the Lifting Surface theory where downwash is conventionally considered to be positive. Similar data blocks are generated for the other 9 spanwise stations. Each spanwise station starts on a new record.

(2) Applicability and Limitations

erscheibereistigenstelleren ertensky frederingen treesteller "blogstelleren en

the second distribution of the second second

See discussion in Section II. 3. a.

Additionally, since the punched output variable -W serves as an approximation to the tangent of the downwash angle when it is utilized as input to the Lifting Surface program, the application of the Jet Flow Field program must be restricted to small angles of attack.

4. APPLICATION OF TRANSFORMATION METHOD TO WING

The transformation method uses the jet-induced velocity components at a number of stations on the wing to determine wing power effects in the form of surface pressure distributions and integrated force and moment. The transformation method requires that the mapping function for each of the wing sections is known. The jet induced velocity components are determined using the jet flow field program described in Volume 7. The mapping function is determined using the techniques developed in Section III of Volume I.

The generation of the coefficients of the mapping function for the sample problem has been described in Section II. 2. A description of the application of the jet flow field program to the sample problem has been given in Section II. 3. The punched card output of the jet flow field program is compatible with the transformation method and includes the mapping coefficients and jet induced velocity components for each of the wing sections. To complete the input to the transformation method program various flow indices must also be specified. Most of these indices have already been defined in the preceding section.

a. Inputs to Transformation Method for Sample Problem

Shown in Figure 12 are the input data for this sample problem in which the punched outputs from the jet flow field program constitute the major portion. However, to activate the computation two cards must precede this basic input block. There may be none, two or three cards following this block, depending on the specified options.

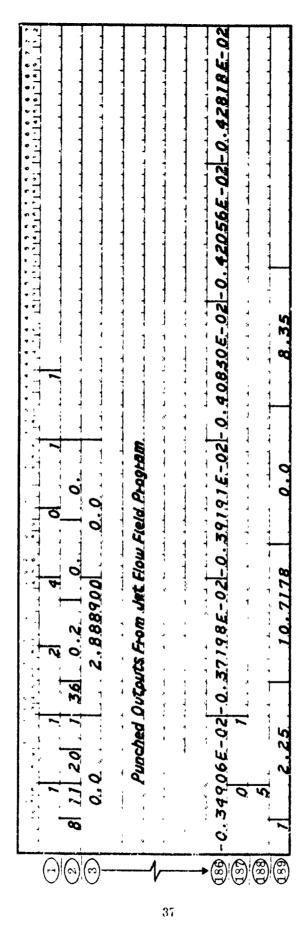

FIGURE 12. TRANSFORMATION METHOD PROGRAM INPUT DATA FOR SAMPLE PROBLEM (Wing)

Card 1 lists in order the classification index (1 specifies a wing), the modification index (1 denotes the option of three-dimensional modification being exercised), the number of iterations, the number of layers for distributing residual sources and sinks, the power index (0 indicates the power effect), the configuration index (1 refers to a nonrectangular wing), and the force index (1 indicates forces and moments to be computed).

Card 2 lists in order the number of stations, the number of pairs of the mapping coefficients, the number of coefficients in the Fourier series expansion, the computation index, the number of angular increments on the mapping circle, the free-stream to the jet velocity ratio, the angle of attack in degrees, and the sideslip angle in degrees.

Cards 3 through 186 contain the punched output data provided by the jet flow field program, which include the y coordinate, the mapping coefficients, and the induced velocity components for stations No. 1 through No. 8. There are 23 cards for each station.

Card 187 lists in order the option index (0 denotes no average value used for the station next to the exhausting jet) and the station number where the jet is located.

Card 188 lists the number of stations on which the downwash modification is to be applied.

Card 189 lists in order the number of jets, the jet exit diameter, X coordinate of the moment center, Z coordinate of the moment center, and the reference length for making the computed moments dimensionless.

b. Outputs from Transformation Method for Sample Problem

Figure 13 lists directly or indirectly a portion of the input data on Card 1 through Card 186.

Figure 14 establishes the correspondence between the angular increments of the mapping circle and their corresponding locations on the wing section at every station. The first column states the angular increments in degrees.

Figure 15 gives the pressure distributions in coefficient form $(p-p_{\infty})_{q_{\infty}}$, at every station after completion of the segment method. These coefficients are tabulated against the angular increments. To obtain the actual location, reference must be made to the previous figure. The second and the third lines in this table list the radius of the mapping circle (RB) and the gradient of this radius in y-direction (DRDY).

Figure 16 lists the pressure distributions at various sections after imposing the residual sources and sinks in the network. Columns 7, 8, 9 in this table remain the same as those in Figure 15, since the flow properties near the wingtip are not modified.

Figure 17 lists the pressure distributions after completion of a three-dimensional modification of one iteration.

Figures 18 and 19 show printout of the pressure coefficients after imposing the residual sources and sinks for the second time and the completion of a three-dimensional modification of two iterations.

Figure 20 lists the parameters used in the three-dimensional modification and in the force and moment computations, originally read in as input data on Cards 187, 188, and 189. Also tabulated are the computed forces (normalized to the thrust) and moments (normalized by the thrust and reference length) on this wing after two iterations.

Figures 21(a) through 21(c) show the comparison between the computed pressure coefficients and wind tunnel test data at stations y = 5.04", 7.2925", 10.545", and 16.0".

Comparison of forces for sample problem with wind tunnel test date of Appendix I is shown in Figure 22, together with further calculations and test data. The calculated power-induced lift follows the trend of the test data. The calculated values show a greater loss in lift than the test data. This is consistent with the surface pressure results shown in Figure 21. The reasons for these differences are not known at the present time.

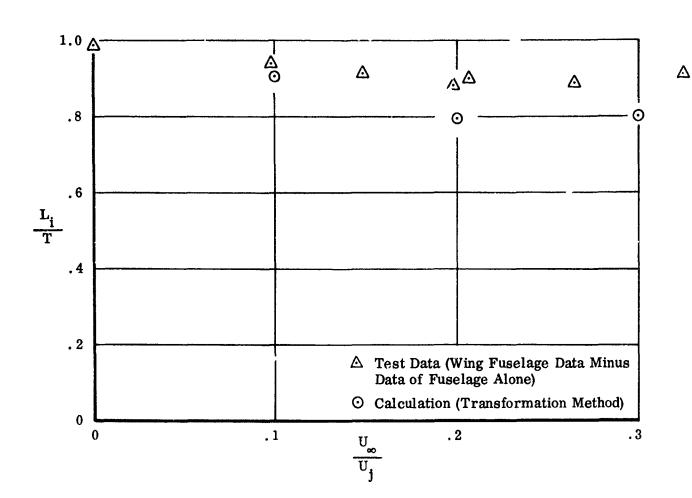

c. Method Applicability and Limitations

This method is generally applicable to power effects on the wing. In addition to the present configuration, fairly extensive calculations on a rectangular wing of aspect ratio equal to 3 with a modified NACA 65-010 section have also been performed (Figure 23(b)). The jet (or jets) was (were) situated at the midspan of the wing and exhausted directly from the lower surface. But the chordwise location of the jet was allowed to vary (three positions: 20 percent, 50 percent and 80 percent of the chord length from the leading edge) and the number of the jets could be one or two. Most of those calculations have been compared with the wind tunnel test data which were obtained at Northrop prior to the present study. Some of these comparisons are shown in Figures 24 and 25.

When the jet exhausts directly from the wing surface, the induced velocity distribution generally shows large and abrupt changes across the jet station. If two iterations are planned these iterations should be smoothed out. Otherwise, the computed results following the second iteration may exhibit unacceptable oscillations. If the calculation is limited to one iteration no smoothing was found to be necessary. Since the lift jet did not exhaust directly from the wing surface in this sample problem, the input data was not smoothed, even though two iterations were computed.

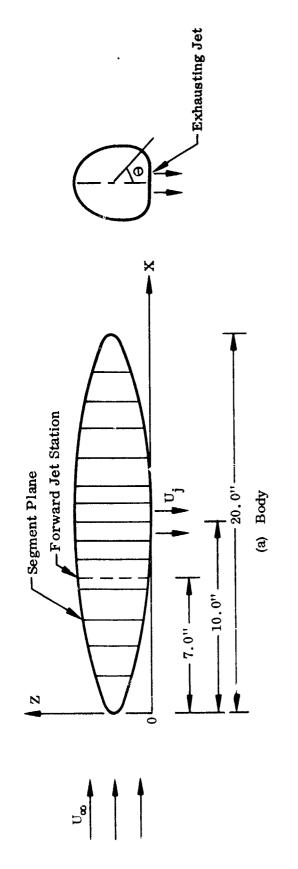

Under the present scheme all the vertical velocity components at any given station, regardless of the chordwise position, are reduced equally to a magnitude of one third of the lifting line downwash value (see pages 101-102 of Volume I for details), Since the aforementioned procedure is somewhat arbitrary some limitations on the method presumably exist. For flow conditions radically different from the present one, the approach given here may have to be modified.

The present method, even when the three-dimensional modification is used, does not include all the three-dimensional effects. The method is, in effect, a quasitwo-dimensional one. Like the widely used quasi-one-dimensional approximation for diffusers and nozzles, its applicability is not as restricted as it may appear. In every example considered, the agreement between calculation and test data is fairly satisfactory. Because of the quasi-two-dimensional nature, however, computations beyond two

iterations may not be warranted. In practice, one iteration is what is usually needed. Two iterations have, nevertheless, been carried out in some selected problems and also in the sample problem here. This is more for demonstration purpose than for utility.

and a separate of same and second and sade of the second o

The present computer program is, in a formal sense, capable of treating both power-on and power-off problems. However, for the power-off case, the wing tips exert a much larger influence upon the flow property than in the case when power effects are being calculated. This important three-dimensional effect has not been adequately accounted for by the present method and the calculations from it are likely to be less accurate. Therefore, the lifting surface theory is recommended under such circumstances.

5. APPLICATION OF LIFTING SURFACE THEORY TO WING

Lifting Surface theory may be utilized to determine the load distribution and aerodynamic coefficients for a given arbitrary planform and specified downwash distribution. The Lifting Surface computer program evaluates power effects on the wing by considering a known, jet-induced downwash distribution.

There are three main components to the program which may be used together in one continuous operation or independently. The downwash control point matrix [D] is generated in the first part of the program, its least squares inverse $[D]^{\Psi}$ is generated in the second part of the program. The pressure distribution produced by the specified downwash matrix [W] is computed by the third component of the program. The downwash control point matrix and its inverse depend only on the planform, the location of the downwash control points and the number of terms in the loading series. Both matrices are independent of the downwash distribution. Once the inverse is computed it forms an input to the third component of the program, where the pressure distribution is computed. Thus $[D]^{\Psi}$ may be retained in punched card form and then used as input for computing the pressure distribution due to specified downwash distributions. The inverse need not be recomputed as long as the planform, location of downwash control points and the size of the pressure loading series remain unchanged.

The Lifting Surface program is a modified version of the computer program for designing and analyzing subsonic lifting surfaces documented in Reference 12. The design options have been eliminated. The capability to calculate pressure distributions produced by a specified cambered surface has also been deleted.

a. Sample Problem Computation

For the sample problem being considered the Lifting Surface program is now used to determine the load distribution and aerodynamic coefficients on the wing, produced by the jet-induced downwash computed in Section II.3.

Figure 26 shows details of the planform of the wing and indicates the location of downwash control points. Figure 26 is identical to Figure 8 of Section II.3, except that all dimensions are now based on a semi-span of unity.

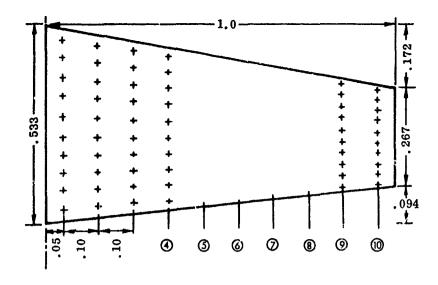

FIGURE 26. DOWNWASH CONTROL POINTS ON WING

(1) Input for Sample Problem

The production of the producti

The input cards required for the sample problem are shown in Figure 27. Since all three main components of the program, discussed in detail above, are being executed in one continuous operation, some duplication of input data occurs.

Card 1 lists two control indices, specifying which of the three major components of the program are to be executed. The combination of ISTART = 1, ISTOP = 3 will execute all three major components. Consequently, the program will start by computing the downwash control matrix [D], will find the inverse $[D]^{\Psi}$ and will compute the load distribution and aerodynamic coefficients.

Card 2 is a title card.

Card 3 lists the number of spanwise stations on semispan where downwash control points are to be located, NS = 10. It specifies the number of spanwise modes to be used in the pressure loading series, M = 6 and the number of chordwise modes, N = 8. The input control index NEED = 1 indicates that the first chordwise mode, i.e., $\cot \theta/2$ mode, is to be used in the computations. The number of leading and trailing edge flaps are specified with NFLAP = 0. The next two integers are print and punch controls for the downwash control matrix [D]. With NPR = 0, NPU = 0, no printed or punched output on [D] will be generated. The print control NAY = 0 specifies that no intermediate print is to be generated during the computation of [D]. The number of leading edge discontinuities 1: pecified as NØLED = 2, and the number of trailing edge discontinuities, NØTED = 2, is indicated.

FIGURE 27. (Concluded)

Card 4 indicates that the chord rise locations of the downwash control points must be specified through input cards at each spanwise station by listing SPACE = 0. It also lists the Mach number, FMACH = 0., and defines the root-semichord F = .2667.

Cards 5 and 6 list the spanwise locations of the downwash control points.

Card 7 may be left blank for a wing with no leading or trailing edge flaps.

Card 8 specifies the tangents of the sweepback angles of the leading edges of the geometric regions.

Card 9 specifies the tangents of the sweepback angles of the trailing edges of the geometric regions.

Card 10 lists the spanwise locations of the leading edge discontinuities.

Card 11 lists the spanwise locations of the trailing edge discontinuities.

Card 12 specifies the number of downwash control points at each spanwise station.

Cards 13 - 22 list the chordwise locations of the downwash control points at each spanwise station (in percent of local chord).

This completes the input required for the first main component of the program, which computes the downwash control point matrix [D].

Card 23 is a title card for the next main component of the program.

Card 24 lists the number of rows in the downwash control point matrix or the number of control points contained in [D], NRØW = 100. It specifies the number of columns in [D], NCØL = 36. This is the product of the chordwise and spanwise pressure modes. The control index NREAD = 0 indicates that the second main component of the program is being executed in a continuous operation and hence [D] will be read from a scratch tape, rather than input cards. With NPR = 0, NPU = 0, no printed or punched output will be obtained for $[D]^{\psi}$, the inverse of the downwash control point matrix. The print control NAY = 0 specifies that no intermediate print is to be generated during the computation of $[D]^{\psi}$.

This completes the input for the second main component of the program, which inverts the downwash control point matrix [D] to obtain $[D]^{\psi}$.

Card 25 is a title card for the third main component of the program which computes the load distribution and aerodynamic coefficients for a specified downwash matrix.

Card 26 lists the number of chordwise modes used in the pressure loading series, N = 6, and the number of spanwise modes, M = 6. It specifies the number of spanwise stations where downwash control points are located, NS = 10, and specifies the number of rows in the downwash control point matrix, NRØW = 100. It specifies the number of spanwise stations where the chordwise pressure loading distribution is to be calculated, NETA = 6. It lists the number of wing discontinuities, NDISC = 2 and the number of leading and trailing edge flaps, NFLAP = 0. The intermediate print control is again NAY = 0. It also specifies the number of chardwise points at which the pressure loading is to be computed, NPSI = 10.

Card 27 lists the number of angles of attack to be treated, NALFA = 1. It also specifies the number of EPSLN's to be read later, NEPSLN = 1. The input control NEED = 1 indicates that the first chordwise mode, i.e., the cot $\theta/2$ mode, is to be used in the computations. The control index NREAD1 = 0 again indicates a continuous operation and thus [D] will be read from a scratch tape rather than from input cards. The next control integer, NREAD2 = 1 indicates that the downwash matrix [W] is read from input cards. The number of downwash distributions to be analyzed is specified with NW = 1.

Card 28 specifies the root semi-chord, F = .2667. It indicates that the chord-wise locations of the downwash control points are specified through input cards at each spanwise station by listing SPACE = 0. It lists the spanwise location of the edge of the fuselage, YF = 0. It indicates how the points at which the pressure loading is calculated are located chordwise, by giving the chordwise spacing DPSI = .1.

Card 29 lists the spanwise coordinates of the downwash control point stations.

Card 30 specifies the spanwise locations where the pressure loading is to be computed.

Card 31 lists the angle of incidence between the centerline of the fuselage and wing root chord in degrees, EPSLN = 0.

Card 32 specifies the angle of attack in degrees, ALFA = 0.

Card 33 may be left blank for a wing with no leading or trailing edge flaps.

Card 34 specifies the chord at each spanwise discontinuity.

Card 35 gives the location of each spanwise discontinuity.

Card 36 lists the distance from root leading edge to the leading edge at each spanwise discontinuity.

Card 37 specifies the number of downwash control points at each spanwise station.

Cards 38 - 57 specify the tangent of the downwash angle at every control point. Cards 38 - 57 are the downwash matrix [W] generated in Section II.3 and shown in tabulated form in Figure 11 of Section II.3.

(2) Output for Sample Problem

With the choice of the punch controls described above, only printed output is obtained.

Figure 28(a) shows a composite of the printout generated by the first main component of the program (CHAIN 1, 8) which computes the downwash control point matrix.

Figure 28(b) shows the printout generated by the second main component of the program (CHAIN 6, 8) which inverts the downwash control point matrix [D]. The determinant of the unit matrix is printed out as a check on numerical accuracy.

Figure 28(c) shows the output from the third main component of the program: (CHAIN 7, 8) which calculates the pressure loading and aerodynamic coefficients.

Geometric parameters of the wing are shown in Figure 28(c) and are all identified. Aerodynamic coefficients and the pressure loading calculated at the spanwise stations specified are shown in Figure 28(c). Again all computed variables are identified.

b. Applicability and Limitations

The program is applicable to continuous surfaces of arbitrary planform and no interference effects such as slots, ground effects, large dihedral angles or end plates are included. The program does contain provisions for body effects.

Downwash control points must not be located at or near the leading edge, since the cotangent elements of [D] would become excessively large and dominate the solution for the pressure coefficient matrix [A]. Due to the computing techniques utilized, downwash control points must not be located at discontinuities in the planform and at flap hinge lines.

c. Additional Calculations and Comparison with Test Data

Once the inverse of the downwash control point matrix has been obtained for a particular wing planform, it is a relatively easy task to obtain the power induced aerodynamics for a range of downwash distribution corresponding to different power conditions. Figures 29a through 29g show calculations for the test model, described in Appendix I, compared with test data for a number of power configurations, velocity ratios and angles of attack.

The interference lift for the vectored thrust, forward position, 90° nozzle deflection angle is shown in Figure 29a for a range of velocity ratios. The wing calculations show that, for all velocity ratios, the induced lift L_i (lift with power on minus lift with power off) is less than for the static case that is, $U_{\infty}=0$. In contrast the test data for wing plus body indicate that there is a lift augmentation at the higher velocity ratios. For nozzle deflection angles of 45° (Figure 29b), although there is now no positive jet interference lift at the higher velocity ratios, the induced lift from the test data is nearly constant for $.3 \le U_{\infty}/U_{j_0} \le .5$, whereas the calculations indicate the induced lift decreases as the velocity ratio increases.

For both the above cases the induced lift was determined from the test data using the inlet plugged as the unpowered case. With the inlet open the mainstream flow through the ejector produces a "power" effect which can be quite large as indicated in Appendix I.

The body alone lift, with power on, for the vectored thrust, forward position, 90° nozzle deflection angle is shown in Figure 29c. Since this configuration was not tested with the inlets plugged, it is not possible to determine the induced lift. However, due to model symmetry, it is reasonable to assume that the power off plugged inlet lift will be quite small and so that the induced lift graph for the body alone configuration will be very similar to Figure 29c.

The positive lift arises due to power induced uploads on the nacelles and body ahead of the jet exits. If this lift increment is subtracted from the wing-body test data, we get very good agreement with the wing calculations.

Figures 29d and 29e show comparisons between the calculations and test data for the aft nozzle positions with two vectoring angles. For the aft position the body alone power effects are expected to be smaller than for the forward position due to the jet exhausts being farther removed from the nacelles. The agreement between test and calculations is seen to be extremely good for all velocity ratios.

Figure 29f shows calculations of the induced lift on the wing with the lift jet operating at a velocity ratio of .20 for a range of α . For $\alpha \leq 8^{\circ}$, Li/ $_{T}$ and hence

 C_{Li} (induced lift coefficient), is effectively independent of α . For larger α the calculated induced lift is still approximately constant whereas the test data shows a sudden increase in induced lift. This is due to a change in the stalling characteristics for the wing, deduced from the pressure measurements, brought about by the jet induced flow field producing a downwash over the wing for this particular jet arrangement and velocity ratio.

A STATE OF THE STA

This result identifies an area in which care must be taken in using the prediction methods. It has been assumed that one can calculate power effects and add these to the unpowered aerodynamics of the vehicle. This procedure of superposition appears to be justified for the linear range of α , but must not be used for nonlinear α . Instead, these two effects must be considered together for nonlinear α . It is possible that the induced flow field due to the power could be included in the nonlinear wing aerodynamics procedure presented in Section VII of Volume I but this has not been studied under the present investigation.

Similar observations may be made for the vectored thrust configuration. Calculations and test data are shown in Figure 29g.

Calculations of pitching moment due to power effects show that there is a nose up pitching moment for body alone, the magnitude of which does not change noticeably with the addition of the wing. This result is in agreement with the calculations.

SECTION III

POWER EFFECTS ON THE FUSELAGE

The calculation of the jet induced loads on a fuselage is accomplished by using the transformation method with the disturbance velocities at the surface of the body calculated by the jet program. To use the transformation method, it is necessary to map the body at different body stations. This section describes the application of these methods to the calculation of fuselage loads.

1. SAMPLE PROBLEM

To demonstrate the application of the methods, the fuselage of the wind tunnel test model which was tested during this investigation will be used. This fuselage is described in Appendix I of this volume. A sketch of the model fuselage with coordinate system is shown below.

The power and flight conditions which must be specified to complete the problem description are as follows:

Jet location (single jet issuing from the fuselage):

$$X_j$$
 = 208 inches
$$Y_j = 0$$

$$Z_j = -30.8 \text{ inches}$$
 Flight Conditions:
$$\text{Jet diameter} = 22.5 \text{ inches}$$

$$\alpha = 0$$

$$\text{Jet velocity ratio } \frac{U_\infty}{U_{io}} = 0.2$$
 $\beta = 0$

All the above dimensions are ten times wind tunnel model dimensions, as will be the case throughout this section.

Jet inclination angles:

the state of the second second second second second second

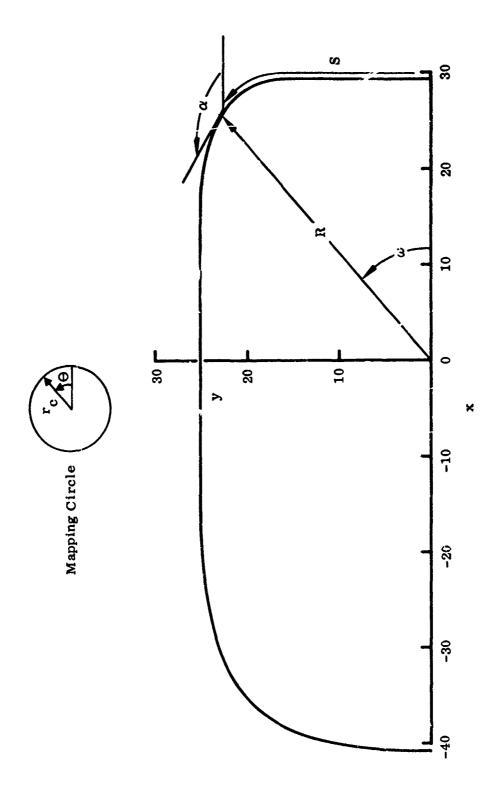

The jet will be taken to be exhausting along the negative Z direction for the sample problem.

2. APPLICATION OF THE MAPPING METHOD

A complete description of the fuselage will not be given here since this is not necessary to describe the application of the mapping method. Instead, a complete treatment of one section of the body will be given, this being sufficient to demonstrate application of the method.

Figure 29 shows the section of the wind tunnel test model body at station 264.25 together with terminology for mapping into a circle. This section has been rotated 90° counterclockwise so that the axis of symmetry is along the X-axis with the bottom of the section cutting the positive X-axis. This coordinate system is not related to the original fuselage coordinate system but is in the terminology used in the mapping program. This location of the section is the proper one for the mapping method, and the mapping coefficients obtained with this orientation are in the correct form for the transformation method. Figure 30 shows the inputs to the mapping computer program required to obtain a mapping of this section.

The first card contains four integers. The first of these number specifies the number of points specified about the section. The second number s, ecifies the number of corners around the section (for a symmetrical section this would represent the number of pairs of corners except for corners on the X-axis), which for this section is

The second and the second second

zero. The third number represents the number of terms in the expansions for the potential and for the mapping function. The last number on this card specifies that the section being mapped is symmetrical.

Cards 2 through 6 specify the X-coordinates of the (in this case) 37 points being taken about the section starting on the positive X-axis and ending on the negative X-axis. Cards 7 through 11 specify the Y-coordinates of these same points on the section.

Since there are no corners to be specified on this section, the next number (on card 12) specifies what shift is desired to translate the body along the X-axis. In this case there is no need to shift the section location as it is sufficiently well centered.

the design of the and where the contest and the second transfer of the second of the second second of the second o

Card 13 specifies inputs needed to specify parameters for the numerical integration of the mapping function obtained. The first two numbers specify the X- and Y- locations of the initial point of the mapping.

The next three numbers specify the angular rarge (about the mapping circle) of points to be obtained on the section, and the approximate spacings to be obtained. In this case it is specified that points from 0° to 180° around the mapping circle are to be calculated and are at an interval size of 5°.

Card 14 specifies a similar set of parameters for the analytically integrated mapping. It specifies that 37 points are to be obtained with a spacing of 5° of theta and that the points are to start at $\theta = 0^{\circ}$.

Figure 31 shows the output of the mapping program. These outputs have been described in Section II.2 and so will not be further explained here.

Figure 32 shows a plot of the mapping as obtained by analytical integration. A comparison of Figure 32 and Figure 29 shows that the mapped section must be shifted 4.42 inches in the negative X direction to give the best fit. This, then, is the value of the constant term in the mapping.

The complete tabulation of coefficients for the wind tunnel test model body with canopy off are shown in Table II. The values of dr_c/dx , the rate of change of the mapping circle radius with body station, have been obtained by graphical differentiation of r_c plotted versus x. In addition to the coefficients tabulated in Table II, the initial mapping coefficient a_1 , required as input to the jet program, is equal to 1.0 for all the fuselage stations.

3. APPLICATION OF JET FLOW FIELD THEORY TO FUSELAGE

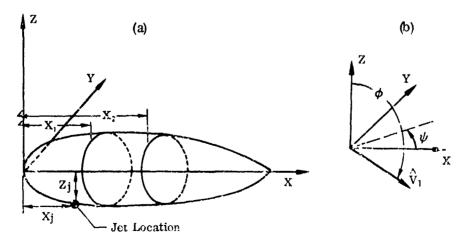

The purpose of the Jet Flow Field theory, when used in conjunction with the Transformation Method, is to predict jet-induced velocity components at the control points on the fuselage required by the Transformation Method to evaluate power effects. This is accomplished by executing the Jet Flow Field program to generate required data for the Transformation Method in the form of punched data cards. To insure compatibility with the Transformation Method, the control points on the fuselage where induced velocity components are to be computed are specified by utilizing the mapping coefficients for the fuselage cross sections obtained in Section III.2. The punched output is generated in a manner providing a continuous block of input data to the Transformation Method computer program. Both of the above points will be described in greater detail in the discussion of the sample problem computations.

It should also be noted that the application of the Jet Flow Field program to provide data to the Transformation Method program for the computation of power effects on the fuselage, differs only slightly from its application to computing power effects on the wing, discussed in Section II.3. Consequently, much of the discussion below will parallel that of Section II.3.

a. Sample Problem Computation

the foreign to be a made a considered to the considered and a considered to the constant of th

For the sample problem being considered, the Jet Flow Field program is now used to compute the jet-induced velocities at the 16 fuselage stations described in Section III. 2. A sketch of the fuselage and the location of the jet with respect to the input/output coordinate system is shown below. The jet exhaust angles ϕ and ψ are also defined.

(1) Input for Sample Problem

The input cards required for the sample problem are tabulated in Figure 34.

Card 1 lists three control indices. The first one, MULT = 1, indicates that a single jet configuration is being treated. The second one, IGEØM = 2, specifies that control points on fuselage cross sections will be generated utilizing the mapping coefficients obtained. The third control index, IPUNCH = 1, generates the punched output for the Transformation Method program.

Card 2 specifies angle of attack, $\alpha = 0$ and angle of sideslip, $\beta = 0$.

Card 3 controls the number of steps and the step size in the numerical integration of the equations of motion for the jet path. For the sample problem, 90 steps with a step size of .4 (jet exit diameters) are chosen.

Cards 4 and 5 contain information about the jet. The jet location, in the coordinate system of Figure 33, is X = 208., Y = 0, Z = -30.8. The jet exhaust angles ϕ and ψ , defined in Figure 33(b), are 180 and 0 degrees, respectively. The jet exit diameter, $d_0 = 22.5$ and the velocity ratio, $U_{\infty}/U_{10} = .2$.

Card 6 may be left blank for single jet computations. For a multiple-jet configuration it would be used to control the geometry of the jet resulting from the intersection of two other jets.

The remaining input cards provide data to generate the control points at which jet-induced velocities are to be evaluated. These control points, in order to insure compatibility with the Transformation Method, are generated by utilizing the mapping coefficients and mapping circle radii obtained for the 16 fuselage stations of the sample problem. The number of control points generated at each fuselage station is governed by the input variable, NTHT, which is the number of increments $\Delta\theta$ into which the mapping circle (or mapping semicircle if only half the fuselage is to be mapped at each station) is to be divided in the Transformation Method computer program. Since the flow is symmetric ($\beta = 0$), computations will be carried out for only half the body. Consequently, the number of control points at each fuselage station will be NTHT + 1.

Card 7 specifies that NTHT, the number of equal increments $\Delta\theta$ into which the mapping semicircle is divided, is 18, which will generate 19 control points at each fuselage station. It defines the number of fuselage stations NS = 16. It also defines the number of terms used in the mapping expansion, NCOEF = 11, and through the control index NSYM = 0 indicates that computations are to be effected for only half the fuselage at each station.

FIGURE 34. JET FLOW FIELD PROGRAM INPUT DATA FOR SAMPLE PROBLEM (Fuselage)

The data in cards 8-55 are taken from Table II, which is determined in Section III.2.

Cards H-10 provide the data from which the fuselage cross section at the first station can be generated by the computer program. Card 8 specifies the location of the station, X = 23.7, the mapping circle radius R = 10.2633, and the rate of change of R with X, DRDX = .285.

Cards 9 and 10 list the real parts of the coefficients to be used in the mapping expansion (thus only symmetrical fuselages may be treated).

Cards 11-55 are similar data blocks for fuselage stations X = 41., 73., 94., 118., 143.5, 163.5, 185.5, 221.5, 264.5, 316., 343., 374., 411., 450., and 497.

Note: The rate of change of the mapping circle radius with distance along the fuselage, DRDX, is not required for any of the computations performed by the Jet Flow Field program. It will, however, be required by the Transformation Method program, and is read as part of the input so that it may be punched out in the proper sequence in the data package to be provided to the Transformation Method program.

(2) Output for Sample Problem

For the sample problem being considered, both printed and punched outputs are obtained.

Printed Output

Figure 35(a) shows the first page of printout. The jet configuration being treated is identified both by appropriate heading and by printout of pertinent input information. Input controlling the numerical integration procedure is also displayed. Figure 35(b) shows a partial printout of computed jet centerline information. The coordinates of the jet centerline are identified. The nondimensionalized jet speed U_j/U_{j0} and the nondimensionalized major diameter of the ellipse representing the cross section of the jet, d/do, are also printed out. These properties are printed out at each integration interval as specified on card 3 of the input. The variables XCOORD and DIA show a monotonic increase over this region, while $U_J = U_j/U_{j0}$. Ponce the jet speed U_j approaches the freestream speed U_∞ . Figure 25(c) shows the printout for the jet-induced velocity components at the first fuselage station specified, X = 23.7. The coordinates of the 19 control points at the station are identified. For this symmetric flow sample problem, only the positive half of the fuselage station is generated. The induced

This is a star of the content of the

FIGURE 35(c). INDUCED VELOCITY COMPONENTS AT STATIONS 23,7 AND 497.

velocity components U, V, W, all nondimensionalized by U_X , are printed out for each control point. Figure 35(c) also shows the printout for the last fuselage station considered in this problem, X = 497. Similar printouts are obtained for the other intermediate stations specified as part of the input.

Punched Cutput

and the particular of the type of the temperature and the second to the second temperature and temp

The punched output for the sample problem is shown in tabulated form in Figure 36. The output data block for the first fuselage station is identified. The first card lists the fuselage station X = 23.7, the mapping radius R = 10.2633 and the rate of change of R with X, DRDX = .285. The next two cards list the real parts of the coefficients used in the mapping expansion. Cards 4-7 list the induced velocity components in the X-direction for each of the 19 control points at fuselage station X = 23.7. The induced velocity components in the Y-direction are listed on cards 8-11 and cards 12-15 specify the induced velocity components in the Z-direction. Datablocks of this type, each consisting of 15 cards, follow for each of the other 15 fuselage stations specified as part of the input. The punched output is identified in columns 73-80. The fuselage station number is shown in columns 75-77. Sequence numbers for each station appear in columns 78-80. The letters U, V, W and column 74 identify the velocity components listed on the data cards.

Note: From the tabulations of Figure 36 it is apparent that the first three data cards of 'be data generated for each fuselage station represent an exact cuplication of input cards described previously. They are generated as part of the punched output so that a more complete data block for the Transformation Method program may be obtained without additional card handling.

b. Applicability and Limitations

See discussion on applicability and limitations in Section II. 3.

FIGURE 36. (Concluded)

4. APPLICATION OF TRANSFORMATION METHOD TO FUSELAGE

This section bears close resemblance to the discussion in Section II.4 of "Application of Transformation Method to Wing." A finite wing is also a three-dimensional body but it has a distinctive property of generating lift in a uniform stream. Thus, by ignoring a part of the computer program which is concerned with circulation, the power effects on a fuselage are calculated in a manner similar to that for a wing.

a. Inputs to Transformation Method for Sample Problem

All the input data for this sample problem are shown in Figure 37. The punched outputs from the jet flow field program again make up the major portion of the input. Two cards must also precede this basic input block to specify various flow indices, and none, two or four cards may follow this block, depending on the options.

Card 1 and Card 2 denote the same number of flow indices as those on Cards 1 and 2 in the previous section on application to a wing. The meaning of each input is also the same, except that the numer 1 quantities of the following indices are different. The classification index (IGECM) is now equal to 2 to denote a fuselage, the number of iterations (JSTOP) is 1, the number of stations (NSTA) is 16, the computation index (NSYM) is 0 to indicate the existence of a plane of symmetry, and the number of angular increments from 0 to π (MTHET) is 18.

Cards 3 through 242 contain the punched output data furnished by the jet flow field program, which include the X coordinate, the mapping coefficients, and the induced velocity components for stations 1 through 16. There are 15 cards for every station.

Card 243 specifies the station number immediately preceding the exhausting jet.

Card 244 refers to the X coordinate of the fuselage tail.

Card 245 lists in order the number of jets, the jet exit diameter, X coordinate of the center of gravity, and the reference length for nondimensionalizing computed moments.

Card 246 denotes in order the Y coordinate of the nose, Z coordinate of the nose; X coordinate, Y coordinate and Z coordinate of the tail.

U. Outputs from Transformation Method for Sample Problem

The second second

Figure 38 lists directly a portion of the input data on cards 1 through 242.

FIGURE 37. TRANSFORMATION MELHON TROGRAM INPUT DATA FOR SAMPLE PROBLEM (Fuselage)

Figure 39 establishes the correspondence between the angular increments of the mapping circle and their corresponding geometric locations at every fuselage station. The first column gives the angular increments in degrees.

Figure 40 shows the pressure coefficient distribution at each station after application of the segment method. Since these coefficients are tabulated against angular increments only, cross reference to Figure 39 is needed in order to establish pressure distributions in the physical plane.

de de la desta de la proposición de la

Figure 41 is also a table for the pressure distribution similar to the one in Figure 40 but after the three-dimensional modification has been introduced.

Figure 42 gives the parameters used in the three-dimensional modification and in the computation of forces and moments, originally read in as input data on Cards 243 through 246. The computed forces (normalized to the thrust) and moments (normalized by the thrust and reference length) on the fuselage after one iteration are also tabulated in the same figure.

Some of the computed results of this sample problem have been compared with the available wind tunnel test data and are shown in Figures 43(a) through 43(d). The power-effect pressure distributions in these figures are representative for fuselages with a lift jet in a uniform flow. The typical feature of this class may be described as follows: The power effect in the fore part of the fuselage is generally very small, as seen in Figure 43(a). As we approach the lift jet, there is a small region in the front where the power effect is positive (Figure 43(b)). The negative power effect then decreases rapidly and its magnitude becomes very large in the immediate neighborhood of the jet but tapers off to a constant level in the distance of one or two jet diameters. This constant level of power effect is in general quite high and prevails over the entire back part of the fuselage (Figures 43(c) and 43(d)). Thus, it contributes a naior portion of the forces and moments. The origin of this effect is due mostly to the wake formed behind the lift jet. Its prediction lies beyond the scope of the present method. Consequently, the discrepancy between the calculation and the test data in this region is large.

When the sideslip angle is not zero, the jet wake region does not completely enfold the back portion of the fuselage. The comparison between the prediction and the test becomes more favorable as may be seen in Figures 44(a) to 44(c).

Further calculations and wind tunnel test data are compared in Figures 45 and 46. The body referred to in Figure 46 is the one tested at Northrop prior to the present contract (see Figure 23 in Section II. 4).

c. Method Applicability and Limitations

As pointed out in the beginning of this section, the method for predicting power effect on a fuselage is very similar to that of a wing. However, for the sample problems considered in this Volume, there are two differences between fuselage and wing computations. The first one is the formation of a wake behind the exhausting jet which engulfs a large portion of the fuselage and is a fundamental problem. The second difference is computational, and may be briefly described as follows: The induced velocities usually undergo very large changes across the jet, as discussed previously. These are most noticeable in the mainstream direction, which is also the longitudinal direction of a fuselage without sideslip. When we invoke numerical differentiations in the longitudinal direction to determine the strength of the residual sources and sinks, these large variations generally magnify the intensity of the sources and sinks and may cause erratic behavior in the final results. This irregularity usually gets worse when higher iterations are carried out, even though some smoothing of the input data is applied. For this reason, two iterations were not performed. To compare the case of a wing, we notice that the largest variation in the induced velocities exists in the mainstream direction and does not traverse any of the wing stations. In addition, the computational procedure automatically smooths out some of the large variations in the mainstream direction by integration for the "boundary functions" (see Volume I, Section IV, for details) and the subsequent expansion in a Fourier series.

Since the power effect on a fuselage, disregarding the wake, contributes only a fraction to the total power-effect forces and moments, some uncertainty in prediction may be tolerable. Based on this assumption, the segment method is useful since it includes some of the three-dimensional effects that are already present in the jet flow field and gives fairly reasonable results in most cases.

As in the case for a wing, the present computer program is also capable of treating the power-on and power-off problems in a formal sense. However, the three-dimensional effects due to the nose and the tail of the fuselage are not included.

In the examples calculated so far, no smoothing procedure was used for the input data.

SECTION IV

POWER EFFECTS ON CONTROL SURFACES

To predict the aerodynamics of a V/STOL aircraft it is necessary to be able to predict the effects of power on the horizontal and vertical tail surfaces. This power effect can be attributed primarily to an induced flow angle at the tail location. Having a method of predicting the power induced flow angle it is then possible to estimate the aerodynamic forces and moments induced on the tail surfaces by the exiting jet. This section will describe how to obtain the jet induced flow angles at the location of the tail surfaces.

1. SAMPLE PROBLEM

Attribut himosophise edition production of the consistence of the best of the section of the book attributed at the section of the section of

The sample problem to demonstrate the calculation of the downwash at the tail will be the wind tunnel test model described in Appendix I, with the lift jet operating. The jet parameters and the flight conditions are the same as specified in Section III, except that here three values of U_{∞}/U_{10} will be considered .1, .2, and .3.

Power induced downwash and sideslip will be computed at the test rake location:

x = 44.23 inches

y = -6.75 inches

Dimensions in model scale

z = .9, 2.9, 4.9, 6.9, 8.9, 10.9, 12.9 inches

2. APPLICATION OF JET FLOW FIELD PROGRAM TO CONTROL SURFACES

The use of the jet flow field program consists of specifying the points at which jet induced velocity components are to be computed, details of jet location and the flight variables. A description of sample input and output for the jet flow field program has been given in Section II.3. The application of the jet flow field program to the tail problem differs only in the location of the control points.

In this example the down—ash and sidewash angles will be computed at the rake location instead of the vertical or horizontal tail location since test data exists for the rake location.

Figures 47 and 48 show a comparison of power induced downwash and sidewash obtained by the jet program and compared with wind tunnel test data for the body alone with the rake attached. The theory will not account for the presence of a body or a wing so it must be assumed that these components can be ignored in calculating the power induced angles. The agreement shown in the figure can be considered satisfactory considering the scatter in the test data.

3. CALCULATION OF POWER INDUCED FORCES AND MOMENTS ON CONTROL SURFACES

To calculate the incremental force and moments induced on the tail it is necessary to estimate the C_{L_α} of the surface in the presence of the fuselage (and other tail panels) and the cent.oid of the panel load. These values may be estimated by empirical methods such as are to be found in DATCOM. When these values are known, the jet induced downwash and sid wash can be used to estimate an incremental angle of attack or side-slip on the surface in question. From these values it is possible to estimate power induced forces and moments on the tail surfaces. Some estimates of this nature have been made for the wind tunnel test model of this study but the accuracy with which the incremental forces and moments can be measured from the test data precludes any conclusions as to method accuracy. The comparisons made do show, however, that such estimates are of the right order of magnitude.

SECTION V

APPLICATION OF INLET METHOD

The method of force and moment estimation for normal inlets described in Volume I, Section V, consists of three parts. The inlet induced forces are two parts, lip forces which act in the immediate vicinity of the inlet, and surface forces which act at greater distances. The third part consists of a description of the net thrust of the propulsive device causing the inlet flow. An approximation for a lift fan has been derived, but data obtained from test could be used in place of the model.

The inlet method may be applied to a wide variety of configurations. This versatility is a direct result of the empirical nature of the model. Because of this empirical nature, some comment is required on selection of the parameters used in the equations summarized below.

$$\binom{\text{inlet } +}{\text{net fan thrus}c} = \binom{\text{inlet lip}}{\text{forces}} + \binom{\text{surface}}{\text{forces}} + \binom{\text{net fan}}{\text{forces}}$$

Lip Forces:

$$L_{L} = /\frac{2}{2} A_{f} \left[U_{f}^{2} (1 - A_{f} / 4\pi R_{i}^{2}) + U_{\infty}^{2} (\eta - k^{2}) \right]$$

$$D_{L} = \rho A_{f} U_{f} U_{\infty}$$

$$M_{gL} = -\rho A_{f} U_{f} U_{\infty} (R_{i} / 2) \sin \beta$$

$$M_{mL} = \rho A_{f} U_{f} U_{\infty} (R_{i} / 2) \cos \beta$$

Surface Forces:

$$L_{s} = \sqrt{2} U_{\omega} U_{f} \frac{A_{f}}{\pi} \left[\cos \beta \int_{\ln |R|}^{2\pi} \frac{r}{R_{i}} |\cos \theta d\theta + \sin \beta \int_{-R_{i}}^{2\pi} |\sin \theta d\theta \right]$$

$$+ \sqrt{4} U_{f}^{2} \left(\frac{A_{f}}{2\pi R_{i}} \right)^{2} \int_{-L_{i}}^{2\pi} \left[1 - (R_{i}/r)^{2} \right] d\theta$$

$$M_{ms} = \int_{2}^{2} U_{\omega} U_{f} \frac{A_{f} R_{I}}{\pi} \left[\cos \beta \int_{0}^{2\pi} \left[(r/R_{I}) \cdot I \right] \cos^{2}\theta \, d\theta \right] + \sin \beta \int_{0}^{2\pi} \left[(r/R_{I}) - I \right] \cos \theta \sin \theta \, d\theta$$

$$+ \int_{2}^{2} U_{f}^{2} \frac{(A_{f}/2\pi)^{2}}{R_{I}} \int_{0}^{2\pi} (I - R_{I}/r) \cos \theta \, d\theta$$

$$M_{RS} \stackrel{?}{/2} U_{\omega} U_{f} \frac{A_{f} R_{I}}{\pi} \left[\cos \beta \int_{0}^{2\pi} (1-r/R_{I}) \cos \theta \sin \theta d\theta + \sin \beta \int_{0}^{2\pi} (1-r/R_{I}) \sin^{2}\theta d\theta \right] + \frac{2}{\sqrt{2}} U_{f}^{2} \frac{(A_{f}/2\pi)^{2}}{R_{I}} \int_{0}^{2\pi} \left[(R_{I}/r) - 1 \right] \sin \theta d\theta$$

Fan Flow and Force:

$$U_{f} = \left[\left(C_{t} U_{t}^{2} + \left(\gamma - K^{2} \right) U_{\infty}^{2} \right) / \left(1 + C_{0} S_{CB} / A_{f} \right) \right]^{0.5}$$

$$T_{f} = \frac{1}{2} A_{f} \frac{C_{t}}{1 + C_{0} S_{cB} / A_{f}} V_{t}^{2} - \frac{1}{2} (\gamma - K^{2}) \frac{C_{0} S_{cB}}{1 + C_{0} S_{cB} / A_{f}} V_{\infty}^{2}$$

Summation:

$$L = L_L + L_S + T_S$$

$$D = D_L$$

$$M_R = M_{RL} + M_{RS}$$

$$M_m = M_{mL} + M_{mS}$$

1. SELECTION OF PARAMETERS

a. Inlet Method

In the application of the inlet method, judgement must be used in determining the boundaries of the surface upon which the inlet is assumed to have an effect. The magnitude of the pitching moment due to forward velocity as well as the magnitude and sign of the static moment is a direct function of the size and distribution of the effective area. In simple cases such as the presence of an inlet in the surface of a rectangular wing, it is obvious that the entire surface should be considered in the calculations. In more complicated situations it is presently thought that the area considered for each inlet be defined by a radius measured from the centroid of the inlet to the nearest edge of the body or the nearest barrier to flow, such as a sharp corner. Lift forces are concentrated in the immediate vicinity of the inlet and are not so greatly affected by the definition of the effective area.

The radius R_1 , used to separate the area on which "lip" forces act from the area on which "surface" forces act, is completely arbitrary. The value of R_1 does not affect the final result of the calculation which contains the sum of "lip" and "surface" forces. In a particular calculation it may be convenient to make R_1 correspond to the

actual inlet size or to make R_1 a larger value and minimize the value of the surface force integrals.

Although the integrals appearing in the surface force equations are easily adapted to machine computation, graphical integration or a finite summation using a worksheet such as that shown in Table 3 has been found to be satisfactory. Because the forces are concentrated in the immediate vicinity of the inlet, large angular increments may often be used with little loss in accuracy. For configurations with more than one inlet, the present procedure is to superimpose the effects of the individual inlets without consideration of interaction between inlets.

b. Fan Flow Model

In application of the fan flow model, values of the parameters η and K must be selected. These parameters appear only in the combination η -K² and this combined parameter should be in the range ± 1 .

For deep inlets K may be assumed to be zero. For very thin inlets the value of K will approach unity. Reference (2) shows that K = 0.7 for a relatively deep far-inwing installation.

The dynamic head recovery factor η varies from near unity for deep inlets ⁽³⁾ to zero for thin inlets ⁽⁴⁾. Even for deep inlets, the value of η will fall quite rapidly with forward speed if no flow turning device is present.

The parameter C_t is obtained by fitting static thrust versus RPM curves for a particular fan after values have been selected for η -K² and C_DS_{CB} .

2. EXAMPLES OF APPLICATION

The analytical models are applied to several configurations and indicate characteristics consistent with the data. It is not possible to completely verify the analysis as it is not presently possible to separate the effect of the propulsive wake, present in the data, from the effect of the inlet flow, and it is not yet possible to calculate the exit effect with complete confidence for these configurations. No sample calculations are shown because of the relative simplicity of the model, but the selection of the empirical parameters is indicated.

Although a large amount of data is available for both lift-jet and lift-fan configurations, only lift fan data is considered. Lift-jet inlet effects are relatively small due to the lower mass flows and this may result in inlet force variations of the

same order as data scatter ⁽⁵⁾. The amount of usable data available is further reduced by the presence of a high degree of wind tunnel wall interference in some tests.

The methods have been applied to four configurations:

- 1. fan-in-nacelle (6)
- 2. fan-in-fuselage (3)
- 3. fan-in-wing (4)
- 4. 1/6-scale XV5A⁽⁷⁾

a. Fan Flow Calculations

n der tyre generalisesse megas beeggeness temenesises participation interest sensitivities to another sensitivities

Reference (3) and Reference (4) have been used to substantiate the propulsion model. The static thrust versus RPM curves were fitted for both the fan-in-fuselage and fan-in-wing configurations. Using the value of $C_{\rm t}$ so obtained, fan flow versus forward velocity was calculated and '< compared to experimental values in Figure 50. Both curves are reasonably well predicted.

It should be noted that in matching the static thrust curve, the parameter actually obtained is the combination ($C_t/1 + C_D S_{CB}/A_f$), not C_t . Therefore, variation of the value of $C_D S_{CB}$ does not affect the static values produced by the equations but only varies the apparent value of C_t and the effects of translational velocity through the parameter combination (η -K²/1 + $C_D S_{CB}/A_f$). Thus, it may be possible to fit data while using values for individual parameters which are in error.

b. Fan-in-Nacelle

The fan-in-nacelle model of Reference (6) is indicated in Figure 49. The twelve inch fan was electrically driven and was not equipped with inlet devices or exit vanes to aid in turning the flow. The model was reversed in the wind tunnel and the fan was tested in both leading and trailing positions.

The results yielded by the empirical model are shown in Figures 51 and 52; no exit effects are included in the calculated curves, which include inlet effect, net fan thrust, and unpowered aerodynamics. Available data for similar inlets indicate that the dynamic head recovery factor can be expected to decrease rapidly as free stream velocity increases from the static conditions. Therefore, curves for both total loss and complete recovery are shown. The parameter K was assumed to be zero.

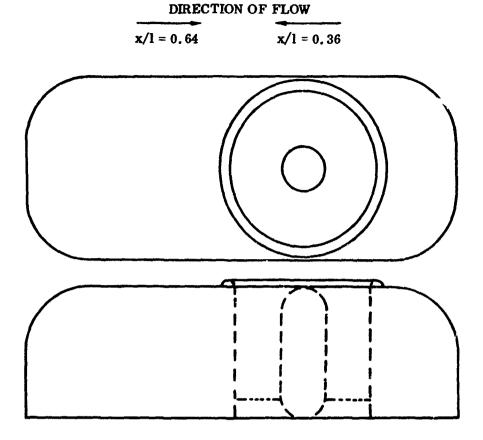

FIGURE 49. FAN-IN-NACELLE CONFIGURATION

The method reflects the change in flow direction as seen in the lift data. Lift forces are reasonably well predicted by assuming high recovery at low speeds and low recovery at high speeds. Drag is also well predicted. The lack of accuracy in the moment prediction may be due to uncertainties in the unpowered aerodynamics, exit effects not included in the predictions, or errors in the selection of the propulsion parameters. Increased fan flow rates would improve overall correlation, but arbitrary changes in propulsion parameters would yield little additional information.

c. Fan-in-Fuselage

The full-scale fan-in-fuselage model of Reference (3) was a shoulder wing configuration of aspect ratio five. The single fan was mounted vertically in the fuselage with the fan axis passing through the wing quarter chord and moment center. A single semicircular vane was placed behind the leading edge of the inlet to improve pressure recovery and inhibit separation. Only tail-off, flap-retracted data are considered.

In the application of the empirical method, the depth of the inlet led to the assumption that the flow is axial to the fan; data shows that pressure recovery of the inlet is nearly complete. Therefore, the parameter $\eta - K^2$ is assumed to be unity.

The diameter of the assumed circular inlet was chosen to contain the intersection of the actual inlet and the fuselage. The projected planform of the wing-body was used in calculating induced surface forces. Inlet sealed data was used to represent power-off terms.

The results of the calculations and data are shown in Figures 53 and 54. Figure 53 compares fan flow rate and fan rotor thrust. Figure 54 shows lift, drag and moment coefficients. It can be seen that drag is best predicted and pitching moment least well predicted. This may, however, be due to the lack of fan exit effects in the analytical predictions.

NASA TN-D-2560 identifies the presence of wind tunnel wall interference in this test and noting that uncorrected data is presented here, removal of the interference would be expected to improve lift correlation. The effect on the moment correlation is not known.

d. Fan-in-Wing

The second state of the second second

Calculations were also made for the one-sixth scale model of the XV-5A reported in Reference (7). The configuration of the test model was gear down, flaps down, and tail off. The model moment center is ahead of the far axis.

In the application of the model, the parameter $\eta - K^2$ is assumed to be zero. The assumed inlet size closely matches that of the actual inlets which are nearly circular. Each fan is assumed to produce induced forces only on the wing panel in which it is mounted. Data obtained with inlet and exit sealed are used to predict power-off effects.

The results are presented in Figures 55, 56 and 57. The empirical prediction is presented both with and without power-off aerodynamics. Fan exit effects present in the test are not included in the empirical predictions. The forces and moments for this test were nondimensionalized by the use of the "slipstream" dynamic pressure q⁸, where:

$$q^s = 0.5 \rho_{\infty} U_{\infty}^2 + L_0 A_F$$

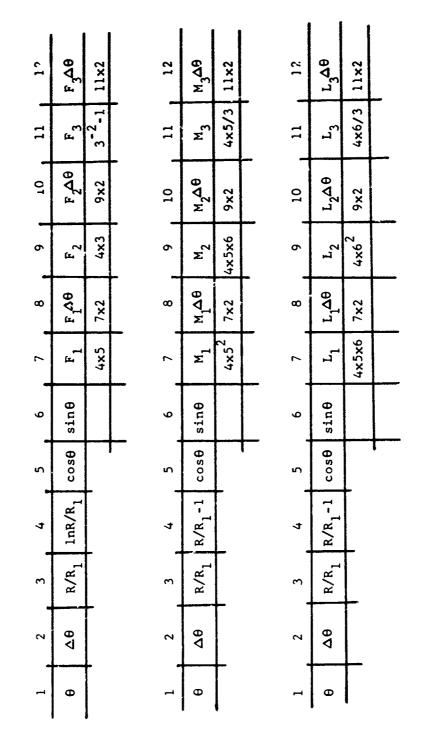

L_o = static lift at constant RPM

$$A_{F} = total fan area$$

Again, arag force is best predicted and moment least well predicted. The addition of exit effects to the prediction should improve the moment correlation and may improve the lift prediction. The use of exit open, power-off data would improve the moment prediction at the expense of lift prediction, due to disturbance of flow on the lower wing surface.

NONLINEAR BODY AERODYNAMICS

The body aerodynamics are computed by combining slender body theory with viscous crossflow effects to obtain nonlinear coefficients at high angles of attack and sideslip. The method, described in Volume I, has been programmed for the computer with the linear and the viscous components of the aerodynamic coefficients printed out separately. The computer program requires that the mapping of the body cross sections be known. This mapping is obtainable by means of the mapping method described in Sections II and III. A simplified method of obtaining inputs to the computer program is also described which permits more ready calculation of body aerodynamics by bypassing the mapping of the body cross sections.

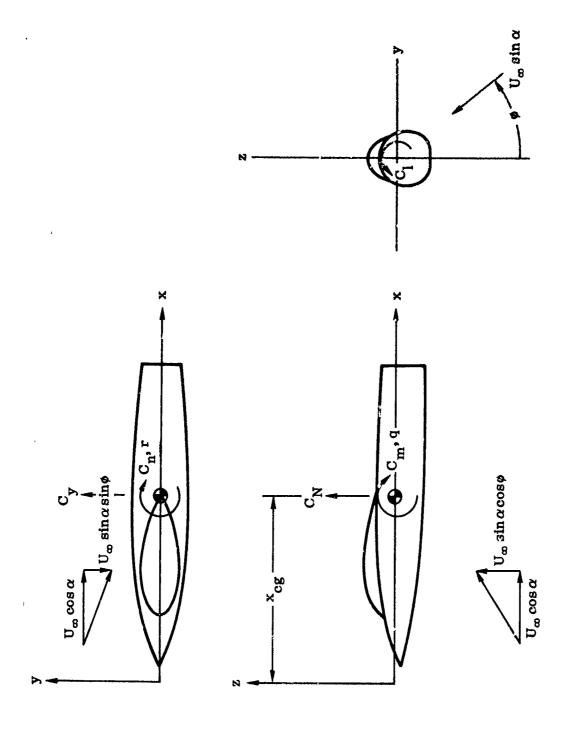

1. SAMPLE PROBLEM

To illustrate the use of the nonlinear body aerodynamics program the wind tunnel test model body described in Appendix I will be used. The aerodynamic coefficients and rotary derivatives will be calculated for this body through an angle of attack and angle of sideslip range.

a. Description of Body Coordinate System

The axis system used to describe the body is shown in Figure 58. The coordinates are body axes with the x-axis aligned along the body. The exact location of the x-axis is chosen to permit the body cross sections to be obtained in planes perpendicular to this axis. The exact location of the origin is not restricted to be at the body nose but may be chosen to suit the user. The axis system chosen consists of a right hand system with the x-axis directed aft, the y-axis to the right and the z-axis upward.

The flight conditions for the static coefficients are specified as a resultant angle of attack α and a roll angle φ . The resultant angle of attack is the angle between the freestream direction and the x-axis and is always defined as positive. The roll angle is then specified as the angle between the freestream component in the y-z plane and the body vertical plane (x-z plane) as shown in Figure 58.

SIGN CONVENTION FOR BODY AERODYNAMIC COEFFICIENTS FIGURE 58.

Of the rotary velocities p is not considered of importance for a body and so is not included in the computation. The rotary components q and r are specified in body with q as a vector in the direction of the positive y-axis and r as a vector in the direction of the negative z axis. This convention was chosen to be consistent with the terminology of Reference 8.

A reference length $\mathbf{1_r}$ reference area $\mathbf{S_r}$ and a center of gravity location $\mathbf{x_{cg}}$ are specified. All of the force coefficients are based on the same reference area. Pitching, yawing and rolling moment coefficients are defined on the reference area and the reference length specified. This differs from the conventional way of defining the moments. The reference point about which the moments are taken is the specified center of gravity location which is located on the x-axis. The effects of including rotary velocities assume that the center of rotations of q and r are at $\mathbf{x_{cg}}$.

The force and moment coefficients are in body axes as shown in Figure 58, C_N positive along the positive z-axis, C_m positive for a moment pitching the nose up. C_y is positive in the positive y direction and C_n positive for a nose right moment. Rolling moment coefficient C_1 is defined positive counterclockwise the moment being specified about the x-axis. No attempt has been made to incorporate the axial force coefficient as the method used is not suitable for that purpose.

b. Body Description for Nonlinear Force and Moment Program

To use the computer program for aerodynamic coefficients the body must be described for a series of sections taken perpendicular to the x-axis. It is not necessary to take the sections chosen at equal intervals but the spacing should be relatively uniform with more sections being taken in regions where the cross sectional parameters are changing rapidly.

The section inputs include both the geometrical variables S and dS/dx and the coefficients of the mapping function and their derivatives. It is therefore necessary to know the mapping of each of the sections being inputed. Although it is necessary to include mapping coefficients, the nature of the slender body theory is such that only the first few coefficients are of primary significance. For this reason it is possible to approximate the coefficients of the mapping function and still retain reasonable accuracy. Therefore, methods are presented for obtaining the mapping coefficients accurately and an easier approximate method which retains the more significant coefficients.

The coefficients as obtained by the mapping program must be modified before they are suitable for use with the nonlinear body aerodynamics program and the method of modification will be described. The simplified method of obtaining coefficients for the mapping function will also be described and a complete set of inputs to the program will be given for this simplified method.

c. Modification of Mapping Function for Body Aerodynamics Program

Equation (1) of Section II is not in the proper form for use with the body aerodynamics program. When this equation is rewritten to include the constant term, i.e., to locate the section

$$Z = \zeta + \partial_0 + ib_0 + \frac{\partial_1 + ib_1}{\zeta} + \frac{\partial_2 + ib_2}{\zeta^2} + \dots + \frac{\partial_n + ib_n}{\zeta^n}$$
(3)

the section is rotated as shown in Figure 59(a). For the body aerodynamics program the tion is rotated as shown in Figure 59(b) and the mapping is commenced at a different point on the section. In addition, instead of basing the mapping on a circle of radius r_c , two mapping is rewritten to base the new mapping on the unit circle coordinate $\sigma = e^{i\theta}$. We final form of the mapping is then:

$$Z = r_{c}\sigma + c_{o} + id_{o} + \frac{c_{1} + id_{1}}{\sigma} + \frac{c_{z} + id_{z}}{\sigma^{2}} + \dots + \frac{c_{n} + id_{n}}{\sigma^{n}}$$

$$\tag{4}$$

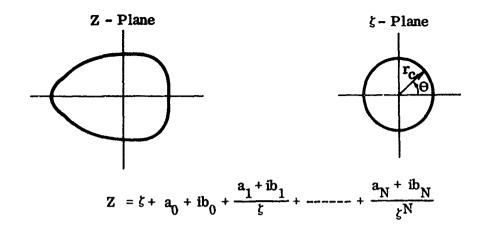

where these coefficients are related to the coefficients of Equation (3) by the relation

$$c_n + id_n = \frac{(-i)^{n+1}}{r_c^n} (a_n + ib_n)$$
 (5)

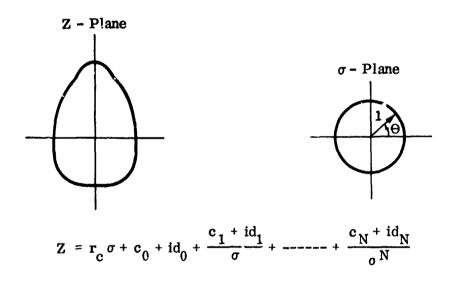

For a symmetrical shape this reduces to the relation

$$Z = r_{c}\sigma - ia_{0} - \frac{a_{1}}{r_{c}\sigma} + \frac{ia_{2}}{r_{c}^{2}\sigma^{2}} + \frac{a_{3}}{r_{c}^{3}\sigma^{3}} - \frac{ia_{4}}{r_{c}^{4}\sigma^{4}} - \cdots$$

$$= r_{c}\sigma + id_{0} + \frac{c_{1}}{\sigma} + \frac{id_{2}}{\sigma^{2}} + \frac{c_{3}}{\sigma^{3}} + \frac{id_{4}}{\sigma^{4}} + \cdots$$
(6)

a. Original Mapping Relation

b. Final Mapping Relation

FIGURE 59. CHANGE OF MAPPING FUNCTION FOR BODY AERODYNAMICS PROGRAM

d. Simplified Handbook Method for Obtaining Coefficients

Since it is desired to use the body aerodynamics program for preliminary design type work it is, where possible, desirable to avoid the complexity of obtaining the mapping function. It is possible to do this for the usual fuselage shapes encountered and still retain sufficient accuracy for preliminary design purposes.

The actual fuselage is replaced by an equivalent body in which the sections are replaced by equivalent ellipses keeping the same body camber. This replaces the mapping of Equation (6) above with the truncated mapping

$$Z = r_c \sigma + i d_0 + \frac{c_1}{\sigma} \tag{7}$$

This expression retains the most critical terms in the mapping as far as obtaining the body aerodynamics and it is possible to approximate the three coefficients \mathbf{r}_c , \mathbf{d}_0 and \mathbf{c}_1 .

Defining a to be half of the maximum vertical dimension of the true cross section and b to be half the maximum lateral dimension of the section, it is possible to approximate r_c and c_1 by the expressions

$$r_{\rm C} = \frac{a_{\rm f} b_{\rm c}}{2} \tag{8}$$

$$c_1 = \frac{b-a}{2} \tag{9}$$

the results being reasonably accurate for fuselages which do not depart too far from the elliptical. The coefficient d_{Ω} can be replaced by the centroid of the sectional area.

The remainder of the inputs required for the slender body portion of the computer program are quantities which can be obtained directly from the body geometry, such as the cross sectional areas and its derivative with respect to x.

e. Viscous Cross Flow Input

The computer program also requires that a cross flow drag coefficient be input for both the components of flow in the vertical plane and the lateral plane.

The viscous crossflow terms can be obtained by using the drag coefficients of an infinite two-dimensional elliptical cylinder at each body station, the character of the ellipse changing according to the maximum dimensions of the body as described above.

These drag coefficients can be obtained using the drag coefficient given in Reference 9 for two dimensional subcritical ellipses and given by

$$C_{D} = .015 \left(1 + \frac{c}{t} \right) + 1.1 \frac{t}{c} \tag{10}$$

where t = maximum dimension perpendicular to crossflow

lands plantik and apply a commission in the constant of the constant is a constant of the cons

c = maximum dimension parallel to crossflow

A coefficient is computed for a crossflow velocity component in the vertical direction in one case and a second coefficient is computed for a crossflow component in the lateral plane. These two coefficients are then multiplied by the maximum dimensions perpendicular to the flow direction for the input parameters.

2. SAMPLE COMPUTATIONS FOR TEST BODY

Table IV shows a set of computations for r_c and c_1 for the wind tunnel test model of this study. The computations are straightforward involving no difficulties. The major inconvenience in developing the inputs for the program is in obtaining S and the derivatives of each of the coefficients with respect to body station. There is no conceptual difficulty involved but the required integration for the body cross sectional area and the centroid location and the graphical differentiations needed to obtain dS/dx, dr_c/dx , dd_o/dx and dc_1/dx is tedious. If necessary, computer programs can be written to do the necessary integration and differentiations but such programs are not included here.

a. Sample Inputs for Force and Moment Program

Figure 60 shows a sample set of inputs for the body aerodynamics program. The data are for the wind tunnel test model body of this study contract with the canopy off.

Card 1 specifies the maximum number of mapping coefficients for any section input (maximum of 12) and the number of stations for which section data is input (maximum of 40).

Cards 2-4 give the station locations of the input sections, maximum of 40. The remainder of the cards must be in units consistent with these numbers. The stations input must not include the nose location nor the tail section if these stations have zero area and mapping circle radius.

Cards 5-7 contain the radii of the mapping circle at the input stations.

Cards 8-10 give the values of $\frac{dr_c}{dx}$ for the same stations.

Cards 11-13 are the cross sectional areas S of the sections.

Cards 14-16 are the values of dS/dx.

Cards 17-19 give the values of the side viscous crossflow drag coefficient per unit length times the maximum vertical dimension at the section.

Cards 20-22 give the vertical viscous crossflow drag coefficient times the maximum lateral section dimension.

Cards 23-76 consist of sets of three cards for each of the input sections (in this case 18 sets). The first card of this set contains two numbers. The first of these specifies the number of mapping coefficients of the given section. If the number specified is zero, the program uses the number given on Card 1. The number given

must not exceed the number on the first card. The second number specifies whether or not the section under consideration is symmetrical or not. If the section is symmetrical, the number 0 is input; otherwise 1. The axis of symmetry is assumed to be the vertical plane.

The second card for each set specifies the coefficients of the mapping function. For a symmetrical section the coefficients input follow the order d_0 , c_1 , d_2 , c_3 , d_4 , c_5 , ... since the other coefficients are zero. For an unsymmetrical section the coefficients are specified in the order c_0 , d_0 , c_1 , d_1 , c_2 , d_2 , ... up to the maximum number of pairs specified. The subscript 0 specifies the second coefficient (or coefficient pair), the subscript 1 the third coefficient, etc.

The remaining cards specify the flight conditions under which the coefficients are to be found. Card 77 is a comment card and can contain any pertinent information desired.

Card 78 specifies four numbers: reference length, 1_r , reference area S_r , center of gravity (and moment center) location x_{cg} and the incremental step size along the body at which computations are made. The program assumes linearity between the incremental steps here specified so that a reasonably large number of steps are required along the body.

The 79th card specifies, respectively, the number of angles of attack to be computed (maximum of 18), the number of roll angles (maximum of 9), number of pitching velocities (maximum of 9) and number of yawing velocities (maximum of 9).

Cards 80 and 81 specify the angle of attack at which the coefficients are to be evaluated. These angles are in degrees.

Card 82 specifies the roll angles which are to be computed, also in degrees.

Card 83 specifies the desired values of pitching velocity inputs. The number inputed represents $q1_{r'2U\infty}$ (dimensionless).

Similarly Card 84 specifies yawing velocity inputs specified as $r1_{r}/_{2U_{\infty}}$ (dimensionless).

This completes the input cards needed to compute the nonlinear body aero-dynamics. Cards are added or subtracted as necessary to input all the specified data. That is, enough cards are used to input the numbers required and no blank cards are to be inputed. As an example, the number of stations here specified is 18 which

requires 3 cards to specify each of the first set of parameters. More of less cards would be used depending on the number of stations specified.

b. Sample Outputs from Force and Moment Program

The Wilder wind the Many retreating to the production of the contract of the c

Figure 61 shows the output from the computer program for the inputs listed in Figure 60. The first line written out in the information input on the comment card.

The second line lists the flight conditions PHI (φ) , $Q\left(\frac{q1_r}{2U_\infty}\right)$, and $R\left(\frac{r1_r}{2U_\infty}\right)$ for which the coefficients are calculated.

After this are tabulated the five coefficients $\mathbf{C_n}$, $\mathbf{C_m}$, $\mathbf{C_v}$, $\mathbf{C_n}$ and $\mathbf{C_1}$ in that order as functions of angle of attack. The coefficients as written out are separated into a potential component (obtained by slender body theory) and a viscous component (using viscous crossflow). To obtain the coefficient these two components must be added together. The program does not calculate a viscous component to the rolling moment so this is printed out as zero.

When more than one set of flight conditions (other than α) are input this tabulation is repeated.

FIGURE 61. NONLINEAR BODY AERODYNAMICS PROGRAM OUTPUT DATA FOR SAMPLE PROBLEM

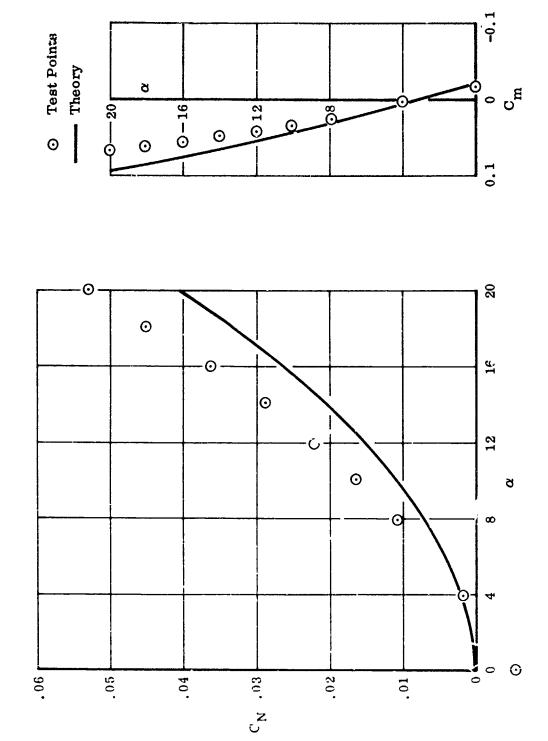

3. COMPARISON WITH TEST DATA

Figure 62 shows the comparison between theory and test for normal force coefficient $\mathbf{C_N}$ and pitching moment coefficient, $\mathbf{C_m}$ at zero sideslip. The theoretically predicted values of $\mathbf{C_N}$ are somewhat low. In particular, the predicted lift curve slope at zero angle of attack is predicted to be zero while the test results show a finite value. The value of $\mathbf{C_N}$ at zero angle of attack is also in error. The agreement obtained for the pitching moment can be considered to be good.

Figure 63 shows a comparison between test and theoretical side force C_y and yawing moment C_n . The theoretical side force tends to be somewhat low, and the agreement in yawing moment is somewhat worse than the pitching moment agreement.

The computer program does not calculate the derivatives but it is possible to compute two sets of coefficients at different values of a parameter and obtain the derivative by dividing the difference of the coefficients by the incremental change in the parameter.

Figures 64 and 65 show samples of rotary derivatives obtained using the computer program. No test data is available with which to compare the theoretical results, so it is not possible to predict what accuracy is obtained by the theoretical method.

THEORY AND TEST CONDITIONS OF C_N AND C_m FOR WIND TUNNEL TEST MODEL FUSELAGE FIGURE 62.

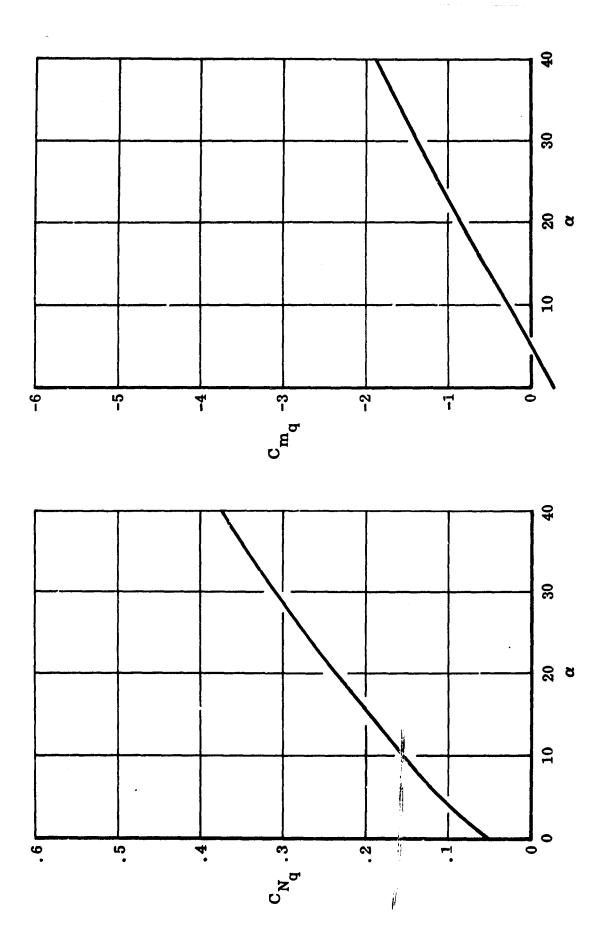

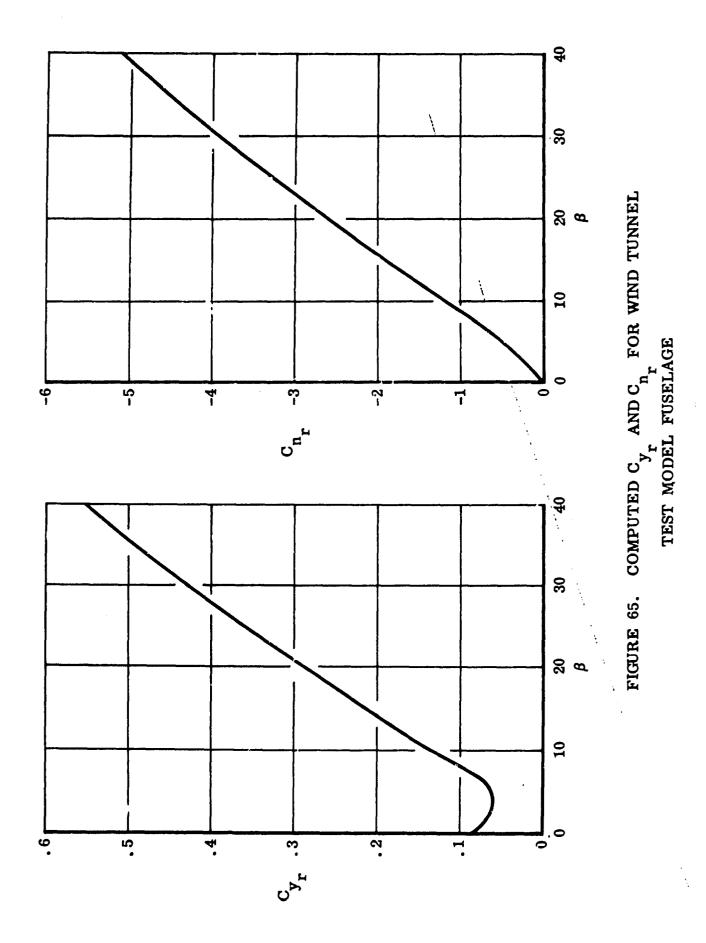

FIGURE 64. COMPUTED CN AND C FOR WIND TUNNEL TEST MODEL FUSELAGE

SECTION VII

NONLINEAR WING AERODYNAMICS

The method used for predicting the nonlinear aerodynamics of wings is that described in Section VII of Volume I. This method has been programmed for the computer and essentially converts the known section characteristics for the wing into finite wing characteristics. First the wing section characteristics have to be identified from available test data. This information is then used to obtain the positions and relative strengths of the two lifting lines. The wing planform and flight condition are included with the section model into the computer program to enable the wing aerodynamics to be determined.

1. SAMPLE PROBLEM

To illustrate the use of the nonlinear wing aerodynamics program the wing for the wind tunnel test model, described in Appendix I, will be used.

The wing planform is shown in Figure 66 with the axes system, lifting lines (discussed later) and downwash control line indicated. The wing employed a NACA 63A010 section.

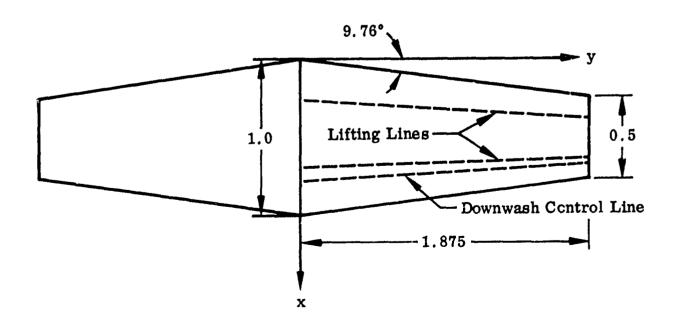

FIGURE 66. WING PLANFORM WITH LIFTING LINES AND DOWNWASH CONTROL LINE SHOWN

The axis system chosen is a right hand system with the x-axis directed aft and the z-axis directed upwards. The flight conditions for the sample problem will be $\alpha = 14^{\circ}$ and 16°, $\beta = 0^{\circ}$ with the rotary variables p, q, r all equal to zero.

a. Determination of Section Parameters

The separation characteristics of airfoil sections are a function of the Reynolds Number, R, the flow tending to separate at a lower value of α , for lower values of R. The unpowered runs in the tests described in Appendix I were at a Reynolds Number/foot = 1.3×10^6 . No data could be found for the test model wing section (NACA 63A010) for Reynolds Numbers as low as the test value. However, data for section NACA 64₁-012, with a similar section geometry, for the required values of R has been determined in Reference 10 and is tabulated in Table V.

The drag coefficient for the airfoil at α = 90° is taken to be 2.08 (value for NACA 0012 airfoil) with the line of action passing through the chord center. The leading lifting line, in the mathematical model for the airfoil section, is positioned at the quarter chord position ($C_{m_1/4}$ = 0 in linear α range). The downwash control point is taken to be at .75 chord. The aft lifting line is now chosen to give a good fit to the section pixning moment while satisfying the boundary condition of no flow through the section at the downwash control station and providing an exact duplication of the section normal force. In this case, by taking the aft lifting line to be located at .70 of the chord, a satisfactory representation to the section characteristics is possible as shown in Table V. The weighting function W_t (weighting of circulation between leading and aft lifting lines) is also shown in Table V. The value of W_t is needed for α = 0 and this is determined by extrapolation of the values for larger α .

b. Inputs to Nonlinear Wing Aerodynamics Program for Sample Problem
A sample set of inputs for the nonlinear wing aerodynamics program is shown in Figure 67.

Card 1 specifies the initial value of wing angle of attack α , angle of sideslip β , and the step size in α all in degrees.

Card 2 provides wing planform information in the form of the y-coordinates (relative to the wing root chord), of the wing root and tip chords, wing taper ratio, and the tangent of the leading edge sweep angle.

Card 3 gives in order, the rolling, pitching and yawing velocities.

Card 4 contains the reference length (relative to the wing root chord), the x-

FIGURE 67. NONLINEAR WING AERODYNAMICS PROGRAM INPUT DATA FOR SAMPLE PROBLEM

and z- coordinates of the center of gravity location.

Card 5 contains the wing section normal force coefficient for $\alpha = 90^{\circ}$ and the x-coordinate of the intersection of its line of action with the airfoil chord.

Card 6 gives the number of circulation and downwash control points.

Card 7 specities the number of angle of attacks to be computed and the number of iterations for each α .

Card 8 indicates whether the wing loading is symmetrical about the x-axis, in this case NSYM = 0 indicating symmetry. (NSYM = 1 indicates asymmetrical loading.)

Cards 9 and 10 list the y-coordinates of the circulation control points and downwash control points.

Cards 11, 12 and 13 specify the x-coordinates (relative to chord) and the tangents of the sweep angles for the leading lifting line, the aft lifting line and the line connecting the downwash control points.

Card 14 contains the effective angles of attack for the downwash control point stations. In this case the values have been determined from the previous calculations for $\alpha = 12^{\circ}$.

Cards 15 and 16 list the values of α in degrees at which the circulation weighting function is tabulated.

Cards 17 and 18 contain the tabulated values of the circulation weighting function determined in this case from Table V.

c. Outputs to Nonlinear Wing Aerodynamics Program for Sample Problem

Figure :8 shows the output from the computer program for the input listed in Figure 67. The flight condition is shown in the form of values for α , ? and p, q, r. The spanwise loading and effective angle of attack at the spanwise stations are shown next. The normal force coefficient and the moments about the y- and x-axes follow. This output, excepting the flight condition variables, is repeated for the number of iterations on α (in this case 2).

This set of output is then repeated for the number of α 's input to the program which in this case is two.

d. Method Applicability and Limitations

The method, as presently programmed, is restricted to straight tapered wings. Because the approach uses lifting lines the method is really applicable to large aspect ratio wings and the accuracy of the predictions will not be as good for lower aspect ratio wings. Flaps may be accounted for by changing the

sectio characteristics for the wing. Calculations of the finite wing aerodynamic characteristics depend on a knowledge of the section characteristics so that in some cases this may be a limitation on the method. The method is programmed to calculate the effects of sideslip and the rotary derivatives although no significant attempt has been made to validate these options.

In typical calculations two iterations are used in the linear range of α and five iterations for nonlinear α . Estimates of the effective angle of attack are determined from previous computations at lower values of α . The initial calculations have usually started with $\alpha = 4^{\circ}$ and effective alpha equal to 2° .

2. COMPARISON WITH TEST DATA

The calculations shown in Figure 68 are for the test model described in Appendix I. The test data for these conditions for comparison were

$$\alpha = 14^{\circ} : C_{N} = .708$$
 , $C_{MY} = .365$
 $\alpha = 16^{\circ} : C_{N} = .665$, $C_{MY} = .375$

Further calculations for an aspect ratio 6 wing are shown in Figure 69 compared with the test data of NASA TM 2-27-29A.

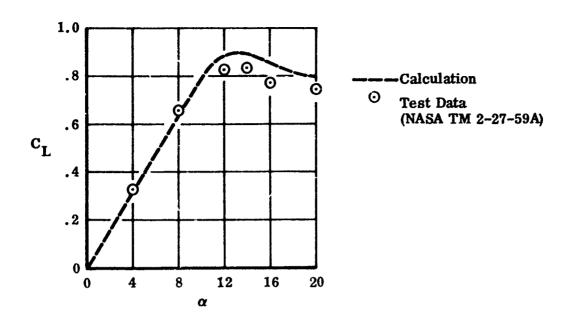

FIGURE 69. WING CALCULATIONS FOR AN ASPECT RATIO 6 WING

APPENDIX I

WIND TUNNEL TESTING OF V/STOL CONFIGURATION MODEL

A model was constructed and tested to supplement the analytical investigative and gain further data for use in validation and improvement of the analytical prediction techniques. The model was configured to resemble a feasible military aircraft but was designed to operate with jets of varied number and location to allow a variety of data to be generated. The test contributes new data because of extensive pressure instrumentation present on the model. These data facilitate identification of the sources of the various induced loads measured during the test.

1. MODEL AND AFPARATUS

The model is a shoulder wing configuration equipped with an external airfoil flap and a stabilator mounted on the vertical tail above the fuselage. Two vectored thrust engines are contained in large nacelles mounted beneath the wing adjacent to the fuselage; a single lift engine is mounted within the body and forward of the vectored exits. The general arrangement of the model is shown in the three view drawing of Figure I-1 and the photographs of Figures I-2, I-3, and I-4. Detailed geometrical data are given in Table I-I.

The vectored thrust engines were simulated by ejector type jet engine simulators. Two 3.67-inch diameter nozzles were tested at two longitudinal positions (11 and 111 percent \bar{c}) at nominal deflections of 0, 45, or 90 degrees at the forward location, and 45 or 90 degrees at the aft location. Larger 4.5-inch diameter nozzles were tested in the aft position at a nominal deflection of 90 degrees. Plugs were used to seal the inlets when rolet flow was not desired.

Typical operating curves for the ejectors are shown in Figure I-5. The design of the ejector nozzles produced a relatively nonuniform jet velocity profile, shown in Figure I-6.

Preceding page blank

The lift jet was simulated by a convergent nozzle supplied through a perforated plate. The exit diameter was 2.25 inches. No inlet simulation was provided. The lift jet possessed a relatively uniform exit profile, shown in Figure I-S.

Details of jet exit location and point of application of resultant forces are shown in Table I-II in terms of location along the mean aerodynamic chord and distance below the wing plane.

The engine simulators were driven by cold dry air supplied through a common plenum fed by a flexible metal tube passing through the sting.

Model forces and moments were recorded using a six-component internal balance.

Two hundred and sixty-four pressure taps are present on the left half of the model. They are placed in four groups: a wing pattern, a lower fuselage pattern, a circumferential pattern at five fuselage stations, a nacelle centerline pattern. Lower fuselage and wing pressure patterns are described in Tables I-III and I-IV. Circumferential fuselage and nacelle centerline patterns are shown in Figures I-7 and I-8.

A seven-probe flow angularity rake was sometimes mounted at the tail station in place of the empennage. Its general arrangement may be seen in Figure I-2.

Testing was performed in the NASA Langley V/STOL tunnel which has a test section of 14 X 22 feet.

2. TEST PROCEDURE

Testing of the model was performed in two phases: calibration of balance and engine simulators, and aerodynamic testing within the wind tunnel.

a. Balance Calibration and Corrections

The testing of a powered model requires additional balance calibration and correction beyond that routinely performed during unpowered testing. The air supply balance arrangement used during this test is indicated schematically in Figure I-9.

Although the air supply line is designed to be highly flexible and cause minimum interference with force measurements, corrections must be applied to balance measurements to reflect that portion of the total load which is carried by the line. A series of known loads was applied to the balance-air supply line assembly, and the resultant balance measurements were used to obtain a matrix of linear correction coefficients.

Pressurization of the system caused forces to be exerted on the model by the flexible supply line. These forces were measured and calibrated with the plenum realed and no nongravitational loads applied to the model. The calibrated forces have been removed from final force data.

The final form of the corrections is shown below. The momentum input due to the supply mass flow was found to be negligible.

$$\widetilde{\mathbf{F}}_{cor} = \widetilde{\mathbf{K}} \ \widetilde{\mathbf{F}}_{bal} - \widetilde{\mathbf{F}}_{p}(\mathbf{P}_{sup})$$

where

 \widetilde{F}_{cor} , a 6x1 matrix of applied loads

 \widetilde{K} , a 6x6 matrix of correction coefficients

 \widetilde{F}_{hal} , a 6x1 matrix of loads measured by balance

 $\widetilde{F}_p(P_{sup})$, a 6x1 matrix of loads applied by the air supply line, calibrated agains, supply pressure

Additional details concerning the magnitude and accuracy of the corrections may be found in Appendix II.

b. Calibration of Engine Simulators

Each engine simulator-nozzle combination was tested individually to determine direct thrust force and moment applied to the model. The same air supply-balance assembly used during tunnel tests was used for this calibration. A calibrated bell-mouth was used to monitor ejector inlet flow. A limited survey was made of nozzle exit profiles to determine their basic character.

These tests were performed with the units mounted on the bare model plenum to minimize static interference effects by reducing surface area near the exits. Some small interference is of necessity present in the data because of the physical proximity of the external portions of the nozzles and drive system.

Lift jet thrust was calibrated on the basis of total pressure within the nozzle. Ejectors were calibrated as a function of primary nozzle plenum pressure. No corrections were made to ejector calibrations due to forward speed present in the tunner. Error due to this approximation is examined in Appendix III.

c. Wall Corrections

CAP interpretation to include a new content of the state of a state of the state of

No corrections were made to the data for possible wall effects. The dimensions of the 14 X 22 foot test section are quite large in comparison to basic model dimensions, and computations, made prior to the test using Heyson's method (11), indicated that wall interference effects would be within the accuracy of the data acquistion system. However, the pitch mechanism used during the test was not capable of maintaining the model at a fixed position within the test section, causing the model to be nearer the floor at the lowest angle of attack tested. An investigation was made to determine if the ground effect of the floor, the nearest surface, was causing any significant effect on the model. The wing-body-nacelle-tail was equipped with the large exits, pitched to a 6 degree angle, and tested at various forward speeds at different heights. An effect was observed a the lowest forward speed tested but not at higher speeds nor statically (see Figure I-10). The minimum raidel height during normal testing was 42 inches. The nondimensionalized minimum neight shown below indicates that the large exits will show the most severe interference at lower angles of attack and low forward speed. The order of magnitude may by two to three percent of total load.

Nozzle	Lift Jet	Small Vector	Large Vector
h/D	13.7	11.4	9.3

d. Test Parameters

The testing of powered models creates a requirement for a parameter relating propulsive and aerodynamic forces. The effective velocity ratio as used in this series of tests is the square root of the ratio of freestream unit momentum flux to mean jet unit momentum flux. It is obtained from the following expression:

$$V/V_{J} = \left[\frac{\rho_{\infty} U_{\infty}^{2}}{\rho_{J} U_{J}^{2}}\right]^{0.5} = \left[\frac{Q}{T/2A_{J}}\right]^{0.5}$$

Another parameter, a relative measure of propulsive and acrodynamic forces, is the thrust coefficient - the ratio of thrust to the product of freestream dynamic pressure and wing area.

$$C_{\tau} = T/QS$$

The two parameters are related in the manner shown below.

$$V/V_{J} = \left[\frac{2A_{J}/5}{C_{T}}\right]^{0.5}$$

The effective velocity ratio is used as the prime parameter of this report because it is less related to the geometry of the particular configuration being considered, and it better describes the state of the highly deflected jet.

e. Test Program

The model was constructed such that nacelles, lift engine, wing, and empennage could be mounted on the fuselage in any combination. Complete model buildups were performed for the wing-body-nacelle-tail configuration powered by the two ejectors in the forward position, and for the wing-body-tail powered by the lift jet. Emphasis was placed on the wing-body nacelle powered by the two ejectors with nozzles in the forward or aft position, and the wing-body without nacelles powered by the lift jet.

A standard series of runs was used throughout the test although not all configurations were tested at all conditions. The series, shown in Table I-V, consists of an unpowered angle-of-attack variation, followed by angle-of-attack variation at several velocity ratios, and velocity ratio variation at fixed angles of attack. A similar pattern was adopted for runs involving sideslip. Both force and pressure data were recorded for most runs.

The range of variables tested included angle-of-attack variations of 0 to 20 degrees, angles of sideslip from 0 to ± 12 degrees, and velocity ratios of 0 to .3 for lift jet powered configurations and 0 to .5 for ejector powered configurations. Very limited testing was performed at combined angles of attack and sideslip. Testing was accomplished at dynamic pressures of 0 to 71 psf, resulting in Reynolds numbers of up to 1.5x10⁶ per foot.

Dynamic pressure and thrust combinations used to achieve these velocity ratios are listed in Table I-VI. Because of tunnel velocity limits, higher velocity ratios were obtained with the use of reduced thrust. Note that these are nominal values. In general, actual thrust levels were slightly lower than those shown.

A summary of configurations tested is given in Table J-VII.

3. Results

as multiple ship and become appropriate the medical properties of the content will be a secretary by the content of the conten

The results of this test are presented in various sections of this report in support of the development and verification of analytical prediction techniques. Complete results will be published in two NASA Technical Memorandums at a later date.

a. Presentation of Results

The force data recorded during the test are presented in several forms:

- (1) Body axis aerodynamic coefficients.
- (2) Stability axis aerodynamic coefficients.
- (3) Forces and moments nondimensionalized by thrust.
- (4) Forces and moments with direct thrust effects removed, nondimensionalized by thrust.
- (5) Forces and moments with direct thrust effects removed, nondimensionalized by dynamic pressure.

In the reduction of aerodynamic coefficients, forces were nondimensionalized by the product of freestream dynamic pressure and wing area. Longitudinal moments were nondimensionalized by the product of freestream dynamic pressure, wing area, and wing mean aerodynamic chord length; lateral moments were nondimensionalized by the product of freestream dynamic pressure, wing area, and wing span.

In the reduction of thrust coefficients, forces were nondimensionalized by the total calibrated thrust of all nozzles operating. Moments were nondimensionalized by the product of total thrust and an effective diameter. The effective diameter is defined as the diameter of a circle equivalent in area to the sum of the exit areas of the operating nozzles.

Thrust removed coefficients were obtained by removing the forces and moments of the operating engine simulators, as determined during static calibration, from the balance measured loads prior to nondimensionalization.

b. Selection of Unpowered Baseline Data

Analysis of the vectored thrust configuration tests has revealed that significant differences exist in unpowered data taken with the ejector inlets open and closed. These differences exceed those directly attributable to vectoring or freestream flow through the undriven ejectors. When these data are used to obtain an interference effect due to jet operation, two significantly different answers result, dependent on which "unpowered" coefficient is used in the calculations.

$$\begin{bmatrix} interference \\ effect \end{bmatrix} = \begin{bmatrix} total \\ load \end{bmatrix} - \begin{bmatrix} direct \\ thrust \\ aerodynamics \end{bmatrix}$$

The effect of the open versus the closed inlet on the power off longitudinal aerodynamic coefficients is shown in Figure I-11 as a function of nozzle deflection angle. Opening of the inlet produces a lift increment of 0.216 with the forward small nozzles deflected 90 degrees. The portion of this increment attributable to momentum change of the free flow passing through the ejectors and nozzles may be found using Figures 1-12 and I-13. The unpowered inlet weight flow is found to be 0.46 lbs/sec/ejector producing an estimated vertical force of 2.43 lbs. This is equivalent to a lift coefficient of only 0.018. Thus, the large part of the inlet lift increment cannot be attributed to flow-through momentum, but must be due to interference with the external aerodynances.

Powered lift data, nondimensionalized by thrust and shown in Figure I-14, do not reflect the significant differences caused by the open inlet in the unpowered data. The difference in powered lift is seen to remain approximately constant at various velocity ratios and, in general, it is small in comparison to the lift loss equivalent to the aerodynamic coefficient increment obtained from power off data. In contrast, the change in inlet mass flow ratio produced by opening the inlet is greater for the powered case than for the unpowered case.

Further examination of the impowered data, as presented in Figure I-15, indicates that the longitudinal coefficients of the inlet open configurations are functions of nozzle deflection angle while those of the inlet closed configuration are not. This observation in combination with the lack of difference in powered data suggests that the unaccounted inlet increment may be due to the exit interactions of the inlet mass flow as opposed to the variation of the inlet condition per se. This conclusion must be considered tentative, however, because the inlet mass flow ratio as well as the exhaust exit angle are varied by nozzle deflection. An examination of the pressure data for this configuration will give more insight to the cause of the open inlet effect on power off data.

Wing pressure differentials are shown for both inlet conditions in Figure I-16. Opening of the inlets causes a pressure change similar to that produced by a positive angle of attack. Examination of both upper and lower surface pressures at WS 10.55,

Figure I-17, indicates that the effect is present on both surfaces, confirming that opening of the index a positive angle of attack change of one to two degrees across the wing, and that the effect is not limited to one of the surfaces.

Pressure distributions about the six fuselage stations are shown in Figure I-18. The data are shown as a locus of pressure normals about the local fuselage contour. Lines within the section indicate positive pressures; lines outside the section indicate negative pressures. At interior corners of the body some data have been eliminated for clarity. The effects of the open inlet on fuselage pressures are noted below.

At the most forward station FG 7.3, the pressure change is similar to that which would be produced by a positive angle of attack of approximately two degrees. Changes occur on both upper and lower surfaces.

In front of the nacelles at FS 11.8, pressure changes on the fuselage sides are dominated by apparent changes in nacelle blockage.

This et plant with the terms with the second of the second

Lower fuselage and nacelle pressures are made more positive in front of the nozzles at stations 11.8 and 19.65. Upper surface pressures are not affected at these stations.

Aft of the nozzles and nacelles at F3 26.425, opening of the inlets induces a more negative pressure on the lower fuselage sides; other areas are not strongly affected. No data are available on the upper surface of the fuselage at this station.

At FS 34.30, a more negative pressure is induced about the section due to opening of inlets.

Upper nacelle centerline pressures, shown in Figure I-19, are unaffected except in the vicinity of the inlet lip. Lower surface pressures are made more positive in the vicinity of the exit.

Lower fuselage centerline data, Figure I-20, indicate that opening of the inlets creates more positive pressures ahead of the exit and more negative pressures aft of the exit.

Data from the tail flow angularity rake indicate increased downwash when the inlets are open, Figure I-21.

In summary, opening of the inlets produces:

THE PARTY OF THE P

- (1) An induced positive angle of at ack on the wing.
- (2) An induced positive angle of awark at the nose.
- (3) Positive pressure increments on the lower fuselage and nacelle ahead of the exits.
- (4) Negative pressure increments aft of the exits.
- (5) Little effect on upper fuselage pressures.
- (6) Increased downwash at the tail station,

These flow changes are consistent with those associated with jet exit interference effects at high velocity ratios and tend to confirm the initial observation that the "inlet" effect is largely caused by the exit of the inlet flow.

Further confirmation can be gained by observation of lower fuselage centerline pressures for the configuration equipped with the large aft nozzles. It can be seen in Figure I-22 that the largest effect of the open inlet occurs in the vicinity of the exit not the inlet. If the differential lower centerline pressures due to the opening of the inlet are plotted against distance from the exit as in Figure I-23, it is seen that data for the forward small 90 degree nozzle and the aft large 90 degree nozzle show a surprisingly strong correlation.

It is concluded that the proper unpowered data for the vectored thrust configurations are that taken with the inlets closed. Data taken with the inlets open, though the model was unpowered in the sense that no drive pressure was supplied to the ejectors, are in fact power on data at a very high velocity ratio, $V/V_j = 2.9$ for the small forward 90 degree nozzle which has been discussed.

BALANCE CORRECTIONS AND CALIBRATION

Calibration of the basic balance was performed by NASA-Langley using well established procedures. The effects of tile air supply line, which spanned the balance, were determined by loading of the balance both with and without the airline using the same series of loads. A matrix of correction coefficients was then derived which caused the corrected airline-on loads to match the measured airline-off or applied loads. The loads were applied through the use of a complex device utilizing a system of weight pans, fulcrums, and levers. The resulting correction factors are shown below. The 6 x 6 matrix indicated in Appendix I is shown here as two 3 x 3 matrices as longitudinal and lateral components were not found to interact.

$$\left\{ \begin{array}{c} \text{Corrected} \\ \text{Loads} \end{array} \right\} = \left\{ \begin{array}{c} \text{Correction} \\ \text{Matrix} \end{array} \right\} \quad \left\{ \begin{array}{c} \text{Measured Loads} \\ \text{Airline-On} \end{array} \right\}$$

$$\left| \begin{array}{c} \text{N} \\ \text{A} \\ \text{M} \\ \text{J} \end{array} \right| = \left| \begin{array}{c} 1.0 & 0 & -.0021 \\ -.0019 & 1.002 & -.0014 \\ .056 & -.0115 & 1.107 \end{array} \right| \quad \left| \begin{array}{c} \text{N} \\ \text{A} \\ \text{M} \\ \text{J} \end{array} \right|$$

$$\left| \begin{array}{c} \text{M}_{\text{X}} \\ \text{M}_{\text{Z}} \\ \text{Y} \end{array} \right| = \left| \begin{array}{c} 1.025 & -.0181 & 0 \\ -.0592 & 1.085 & 0 \\ .0008 & -.0014 & .9960 \end{array} \right| \quad \left| \begin{array}{c} \text{M}_{\text{X}} \\ \text{M} \\ \text{Z} \\ \text{Y} \end{array} \right|$$

$$\left| \begin{array}{c} \text{Bal} \end{array} \right|$$

Because of initial difficulties in obtaining the longitudinal corrections shown above, a second loading of normal force and pitching moment was made with the use of a bar and moving weight pan. This resulted in a different set of longitudinal corrections. Interactions due to axial force were taken from the previous loading.

This matrix differs significantly from the original in the calibration of corrected axial force and pitching moment. The pitching moment difference would cause normal forces to appear approximately . 2 inch farther forward if the second matrix is used in preference to the first. The use of the second matrix would also indicate increased drag with positive normal force and decreased drag with positive pitching moment when compared with data reduced by the first matrix.

The second matrix has been used to reduce the data presented in this report because more experience was available with the method of loading. In addition, the second matrix gave better results on the position of a small test weight and it indicated that the lift jet center of pressure, which was not constant, approached the geometric center of the exit at higher thrusts as opposed to moving away. However, the results of these checks were not conclusive. The matrix below indicates the final matrix of correction coefficients \tilde{K} .

$$\widetilde{K} = \begin{bmatrix} .9945 & 0 & -.00198 & 0 & 0 & 0 \\ .01167 & 1.002 & -.00316 & 0 & 0 & 0 \\ .27 & 6 & 1.109 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1.025 & -.0181 & 0 \\ 0 & 0 & 0 & -.0592 & 1.085 & 0 \\ 0 & 0 & 0 & .0008 & -.0014 & .9960 \end{bmatrix}$$

The matrix shown below will convert the longitudinal data presented in this report to the form it would have had if the original corrections were used.

$$\begin{bmatrix} N \\ A \\ M_y \end{bmatrix} = \begin{bmatrix} 1.0055 & 0 & -.0001 \\ -.0142 & 1.000 & .0016 \\ -.213 & -.0115 & .9975 \end{bmatrix} \begin{bmatrix} N \\ A \\ M_y \end{bmatrix} C_1$$

Nominal accuracy of the basic balance is indicated below.

APPENDEX III

EFFECT OF FORWARD SPEED ON EJECTOR JET ENGINE SIMULATORS

In order to investigate the effect of forward speed on the thrust of the ejector jet engine simulators, the bellmouth used during static calibration was attached to the ejector unit mounted in the test section. The inlet mass flow variation with forward speed was then determined. The effect of forward speed on inlet mass flow is shown in Figure III-1. The changes shown are small, less than six percent, and may reflect changes in the effective area of the bellmouth which was calibrated under static conditions.

erapid madeline in the process of a livertest and a speak manager and interference must be a contract and a surprise and a sur

If the thrust of the ejectors is assumed to vary with the square of the total mass flow, the change in thrust may be computed.

$$\frac{T}{T_0} = \frac{(\rho A_j U_j) U_j}{(\rho A_j U_j) U_{j_0}} = \frac{\dot{w}^2}{\dot{w}_0^2}$$

The computed change in thrust due to forward speed is shown below. The maximum thrust change occurs at the highest forward speed.

Nozzle	T _O , lb	T Max	Q, psf
Small Forward δ _j = 90°	136	1.026	0 - 60
	105	1.026	0 - 60
	80	1.059	0 - 70
	60	1.061	0 - 60
Large Aft ðj = 90°	178	1.001	0 - 60

A greater change occurs at lower thrust levels because of the larger ratio of secondary to primary flow.

The maximum thrust errors are of a magnitude less than twice the nominal accuracy of the normal force beam, and the maximum pitching moment errors are of the same relative magnitude. Correction for the errors would be significant only at the higher velocity ratios tested. At maximum dynamic pressures correction would result in a three percent reduction in velocity ratio and a six percent reduction in thrust nondimensionalized data. As the majority of data show a positive slope at high velocity ratios, the effect is minimized, because the corrected datum tends to move along the established curve.

The state of the s

NORMAL FORCE AND PITCHING MOMENT IN THE LIFT JET WAKE

The jet model includes no mechanism which will account for the wake region behind the jet. Consequently, calculations utilizing the jet flow field program are not in good agreement with test data in this region. As indicated in Section III the wake region contributes the major part of the loads on the fuselage so that it is desirable to have some method for estimating the integrated force and pitching moment for this region.

To enable estimates of the fuselage loads in the wake behind the lift jet to be made, it has been assumed that the difference between test data and calculations in this region is the same as the difference between test data and calculations for the component model of Reference 99.

Thus, for example, if the fuselage is at zero degrees angle of attack and sideslip, the wake contribution to the interference lift, ΔL_i , is given by

$$\frac{\Delta L_i}{T} = \frac{2}{\pi} \left(\frac{U_{o}}{U_{jo}} \right)^2 \iint_{VAKE} \left(\left(C_P \right)_{test} - \left(C_P \right)_{caeculation} \right) \frac{\delta_{WAKE}}{d_o^2}$$

in which T is the jet thrust. This double integral has been evaluated for a range of position along the test fuselage and is shown in Figure IV-1.

The ware contributions to pitching moment may be determined in a similar manner. The results, for the three velocity ratios .125, .2, .3 are shown in Figure IV-2. The moment axis has been taken through the center of the jet.

In Section III adjustments to the calculations have been made to account for the jet wake effect. The jet wake contributions were obtained from Figure IV-1 for a wake length of 13.5 jet diameters.
